CONTENTS

JANUARY

EDITORIALS: I. How long should patients fast before surgery? Time for new guidelines..... 1
L. Strunin

II. Postoperative analgesia in children ... 4
D. Fell

ORIGINAL ARTICLES

Preoperative drinking does not affect gastric contents... 6
S. Phillips, S. Hutchinson and T. Davidson

Pain relief for infants undergoing abdominal surgery: comparison of infusions of i.v. morphine and extradural bupivacaine 10
A. R. Wolf and D. Hughes

Extra inspiratory work of breathing imposed by cricothyrotomy devices 17
R. Ooi, W. J. Fawcett, N. Soni and B. Riley

Evidence for dynamic phenomena in residual tracheal tube biofilm 22
T. J. J. Inglis

Pressure exerted by the laryngeal mask airway cuff upon the pharyngeal mucosa.. 25
R. Marjot

Comparison of the reinforced laryngeal mask airway and tracheal intubation for adenotonsillectomy 30
P. J. Williams and P. M. Bailey

Comparison of alfentanil with suxamethonium in facilitating nasotracheal intubation in day-case anaesthesia.. 34
R. Alcock, T. Peachey, M. Lynch and T. McEwan

Effect of age, gender and anaesthetic technique on the pharmacodynamics of atracurium 38
C. J. R. Parker, J. M. Hunter and S. L. Snowdon

Midazolam–alfentanil: an anaesthetic? An investigation using the isolated forearm technique.................. 42
I. F. Russell

Effects of etomidate on the adrenocortical and metabolic adaptation of the neonate.. 47
T. A. Crozier, C. Flamm, C. P. Speer, W. Rath, W. Wuttke, W. Kuhn and D. Kettler

Nitrous oxide-mediated activation of the EEG during isoflurane anaesthesia in patients...................... 54
A. Yli-Hankala, L. Lindgren, T. Porkkala and V. Jäntti

Comparison of thoracic electrical bioimpedance and thermodilution for the measurement of cardiac index in patients with severe sepsis 58
J. D. Young and P. McQuillan

Differential effects of alfentanil, fentanyl, pethidine and lignocaine administered intrathecally on nociceptive responses evoked by low and high frequency stimulation of somatic nerves.. 63
C. Wang, A. Koutsoukou-Dritsopoulou, M. K. Chakrabarti, A. Holdcroft and J. G. Whitwam

Genetic linkage analysis of chromosome 19 markers in malignant hyperthemia.. 70
S. P. Ball, H. R. Dorkins, F. R. Ellis, J. L. Hall, P. J. Halsall, P. M. Hopkins, R. F. Mueller and A. D. Stewart

In vitro effect of ephedrine, adrenaline, noradrenaline and isoprenaline on halothane-induced contractures in skeletal muscle from patients potentially susceptible to malignant hyperthermia.. 76
A. Urwyler, K. Censier, M. D. Seeberger, J. M. Rothenbühler, M. A. Kaufmann and J. Drewe

REVIEW ARTICLE

The role of recombinant growth factors in transfusion medicine.. 80
L. T. Goodnough

SHORT COMMUNICATIONS

Intra-articular morphine for pain relief after anterior cruciate ligament repair.. 87
G. P. Joshi, S. M. McCarroll, O. H. Brady, B. J. Hurson and G. Walsh

Use of alfentanil with propofol for nasotracheal intubation without neuromuscular block.................. 89
S. F. E. Coghlan, P. F. McDonald and G. Csepregi

Effect of isometric thumb preload on the evoked compound muscle action potential..................... 92
I. Kalli

Glycopyrronium prolongs topical anaesthesia of oral mucosa and enhances absorption of lignocaine 94
H. Watanabe, L. Lindgren, P. Rosenberg and T. Randell

Haemodynamic and metabolic consequences of aortic occlusion during abdominal aortic surgery............. 96
D. G. Whalley, F. C. Salevsky and J. V. Ryckman

Propofol decreases random and chemotactic stimulated locomotion of human neutrophils *in vitro*............. 99
A. G. Jensen, C. Dahlgren and C. Eintrei

CASE REPORTS

Use of transoesophageal echocardiography to manage beta-adrenoceptor block and assess left ventricular function in a patient with phaeochromocytoma 101
T. Ryan, A. Timoney and A. J. Cunningham

Use of esmolol in the postbypass management of hypertrophic obstructive cardiomyopathy.................... 104
L. G. Ooi, P. J. O'Shea and A. J. Wood

Prolonged use of isoflurane in a patient with tetanus.... 107
J. J. W. M. Stevens, R. M. Griffin and P. J. Stow

CORRESPONDENCE

Postoperative pain thresholds 110
Pharmacokinetic/pharmacodynamic modelling of atracurium 110
Sedation with propofol during regional anaesthesia...... 112
Aspirin, bleeding time and central neural block.......... 112
Death certification 112
Ketorolac postoperative analgesia......................... 112
Patient-controlled analgesia by proxy..................... 113
Veterinary use of "Xylocaine" spray 113
Use of the laryngeal mask and face mask by inexperienced personnel 114
Changes in haemodynamic variables with thiopentone, methohexitone, propofol and etomidate 115
Antepartum assessment for anaesthesia.................. 116

BOOK REVIEWS

Adult Respiratory Distress Syndrome 117
Collection d'Anesthésiologie et de Réanimation, Volume 30: Monitorage Non-Invasif en Réanimation 117
MCQs in Anaesthesia: Basic Sciences...................... 117
Key Topics in Anaesthesia 117
Moving to Audit, An Educational Package for Hospital Doctors and General Practitioners........................ 118
Hypoxia, Metabolic Acidosis and the Circulation........... 118

Erratum 119

FEBRUARY

EDITORIALS: I. Upper airway reflexes.................. 121
G. B. Drummond

II. The laryngeal mask airway in paediatric practice.......................... 124
I. G. Wilson

ORIGINAL ARTICLES

Measurement of the sensitivity of upper airway reflexes. 126
J. A. Langton, P. J. Murphy, P. Barker, A. Key and G. Smith

Effect of oral diazepam on the sensitivity of upper airway reflexes.. 131
P. J. Murphy, J. A. Langton, P. Barker and G. Smith

Logistic regression analysis of fixed patient factors for postoperative sickness: a model for risk assessment... 135
M. Palazzo and R. Evans

Comparison of automatic oscillometric arterial pressure measurement with conventional auscultatory measurement in the labour ward 141
M. A. Hasan, T. A. Thomas and C. Prys-Roberts

Use of ultrasound to evaluate internal jugular vein anatomy and to facilitate central venous cannulation in paediatric patients.................................. 145
P. J. Alderson, F. A. Burrows, L. I. Stemp and H. M. Holtby

Metabolic effects of corrective surgery in infants and children with congenital heart defects................ 149
K. Puhakka, J. Räsänen, M. Leijala and K. Peltola

Effect of nitrous oxide on cerebral blood flow in normal humans 154
L. M. Field, D. E. Dorrance, E. K. Krzeminska and L. Z. Barsoum

Neostigmine and edrophonium antagonism of moderate neuromuscular block induced by pancuronium or tubocurarine.. 160
G. D. Shorten, H. H. Ali and N. G. Goudsouzian

Tracheal intubation after induction of anaesthesia with propofol, alfentanil and i.v. lignocaine................ 163
J. A. H. Davidson and J. A. Gillespie

Effects of intradermal lignocaine and mepivacaine on human cutaneous circulation in areas with histamine-induced neurogenic inflammation..................... 167
H. Fruhstorfer and G. Wagener

Anaesthesia affects plasma concentrations of vasopressin, von Willebrand factor and coagulation factor VIII in cardiac surgical patients................................ 173
A. Kuitunen, M. Hynynen, M. Salmenperä, V. Rasi, A. Järvinen, M. Scheinin, P. J. Neuvonen and F. Fyhrquist

Effects of midazolam and flunitrazepam on the release of dopamine from rat striatum measured by *in vivo* microdialysis.. 181
K. Takada, T. Murai, T. Kanayama and N. Koshikawa

Mathematical analysis of the upper respiratory tract from an anthropometric study.............................. 186
G. Janvier, L. Bordenave, P. Revel, W. Ellison, A. M. Cros and S. Winnock

Comparison of recovery from anaesthesia induced in children with either propofol or thiopentone 192
C. J. Runcie, S. J. MacKenzie, D. S. Arthur and N. S. Morton

Acute haemodynamic effect of sodium bicarbonate in canine respiratory or metabolic acidosis 196
T. Nishikawa

Plasma concentrations of bupivacaine and its enantiomers during continuous extrapleural intercostal nerve block 201
R. G. Berrisford, S. Sabanathan, A. J. Mearns, B. J. Clarke and A. Hamdi

REVIEW ARTICLE

The haemostatic response to surgery and trauma 205
W. G. Murphy, M. J. Davies and A. Eduardo

SHORT COMMUNICATIONS

Long-term backache after extradural or general anaesthesia for manual removal of placenta: preliminary report 214
R. J. Vickers and A. E. May

Clinical evaluation of the oesophageal heat exchanger in the prevention of perioperative hypothermia........... 216
P. Kulkarni, A. Matson, J. Bright, J. Pearson and F. Carli

Effects of lorazepam on oxygen saturation before cardiac surgery 219
J. S. S. Pollock and G. N. C. Kenny

Effects of midazolam on insulin secretion from isolated rat pancreatic islets of Langerhans.................... 221
J. P. Desborough, P. M. Jones, S. J. Persaud and S. L. Howell

CASE REPORTS

Visualization of extradural blood patch for post lumbar puncture headache by magnetic resonance imaging... 223
A. G. Griffiths, S. C. Beards, A. Jackson and E. L. Horsman

Muscular paralysis and ventilatory failure caused by hyperkalaemia 226
S. J. Freeman and A. D. Fale

HISTORY

John Henry Hill Lewellin: the first etherist in Glasgow . 228
A. G. Macdonald

CORRESPONDENCE

Neuromuscular blockers in day-case surgery: is speed of onset more important than duration of action? 235
Blood loss during total hip replacement................. 235
Metabolic effects of dobutamine......................... 236
Nitrous oxide administration via oxygen therapy devices 238
Mortality in ITU patients receiving neuromuscular blocking drugs 238
Face masks and spinal anaesthesia....................... 239
Pain on i.v. injection of metoclopramide................ 239

BOOK REVIEWS

Principles and Protocols in Intensive Care 240
Conduction Blockade for Postoperative Analgesia: Mechanisms and Management 240
Techniques in Extracorporal Circulation, 3rd Edn.......... 240
Ward's Anaesthetic Equipment, 3rd Edn 241

Erratum.. 241

MARCH

EDITORIALS: I. Why not model physiologically? 243
J. W. Sear

II. Synergy and isoboles.................. 246
T. N. Calvey

ORIGINAL ARTICLES

A physiological model for the distribution of injected agents, with special reference to pethidine............ 248
N. R. Davis and W. W. Mapleson

Effect on lung volumes of oxygen concentration when breathing is restricted 259
A. B. Baker, A. McGinn and C. Joyce

Effects of PEEP on dynamic hyperinflation in patients with airflow limitation.................................. 267
I. K. S. Tan, S. B. Bhatt, Y. H. Tam and T. E. Oh

Minimum alveolar concentration of sevoflurane in elderly patients 273
R. Nakajima, Y. Nakajima and K. Ikeda

Clinical and radiological comparison of perivascular and transarterial techniques of axillary brachial plexus block 276
P. Pere, M. Pitkänen, M. Tuominen, J. Edgren and P. H. Rosenberg

Improvement in i.v. regional anaesthesia by re-exsaguination before surgery.................................... 280
N. Rawal, J. Hallén, A. Amilon and P. Hellstrand

Pharmacokinetics of flumazenil and midazolam.......... 286
R. D. M. Jones, K. Chan, C. J. Roulson, A. G. Brown, I. D. Smith and G. H. Mya

Diclofenac and ketoprofen for pain treatment after elective Caesarean section 293
M. G. F. Rorarius, P. Suominen, G. A. Baer, O. Romppanen and R. Tuimala

Preoperative indomethacin for pain relief after thoracotomy: comparison with postoperative indomethacin 298
D. F. Murphy and C. Medley

Effects of surgical stimulation on autonomic reflex function: assessment by changes in heart rate variability 301
T. W. Latson and D. O'Flaherty

Haemodynamic and catecholamine responses to induction of anaesthesia and tracheal intubation: comparison between propofol and thiopentone........ 306
L. Lindgren, A. Yli-Hankala, T. Randell, M. Kirvelä, M. Scheinin and P. J. Neuvonen

Plasma catecholamines and neonatal condition after induction of anaesthesia with propofol or thiopentone at Caesarean section 311
T. Gin, M. E. O'Meara, A. F. Kan, R. K. W. Leung, P. Tan and G. Yau

Benzodiazepines and their solvents influence neutrophil granulocyte function 317
M. Weiss, N. Mirow, A. Birkhahn, M. Schneider and P. Wernet

Platelet serotonin is a mediator potentially involved in anaphylactic reaction to neuromuscular blocking drugs 322
N. Bermejo, J. L. Guéant, E. Mata, P. Gérard, D. A. Moneret-Vautrin and M. C. Laxenaire

I.v. bolus administration of subconvulsive doses of lignocaine to conscious sheep: myocardial pharmacokinetics... 326
Y. F. Huang, R. N. Upton and W. B. Runciman

Influence of cardiac output, injection time and injection volume on the initial mixing of drugs with venous blood after i.v. bolus administration to sheep 333
R. N. Upton and Y. F. Huang

REVIEW ARTICLES

Hepatotoxicity of volatile anaesthetics 339
R. H. Elliott and L. Strunin

Perioperative management of the obese patient.......... 349
Z. Shenkman, Y. Shir and J. B. Brodsky

SHORT COMMUNICATIONS

Studies of gastric content: comparison of two methods. 360
E. Søreide, J. A. Søreide, H. Holst-Larsen and P. A. Steen

Accumulation of acetone in blood during long-term anaesthesia with closed systems 363
J. M. Strauß and J. Hausdörfer

Test-tube equilibration of volatile anaesthetic concentrations.. 365
D. C. Martin, J. K. Pruett and R. S. Aronstam

CASE REPORTS

Delayed presentation of an extradural abscess in a patient with alcohol abuse 368
O. Nordström and R. Sandin

Electrode burns during local hyperthermia............... 370
D. G. Stott and W. A. Wallbank

APPARATUS

Comparison of portable emergency ventilators using a lung model 372
L. Attebo, M. Bengtsson and A. Johnson

CORRESPONDENCE

Pre-emptive analgesia..................................... 378
Effect of nitrous oxide on auditory evoked potentials ... 379
Use of lignocaine in ventricular defibrillation?........... 380
Regurgitation and the laryngeal mask airway............ 380
Explaining risk to patients................................ 381
Editorial II—the National Confidential Enquiry into Perioperative Deaths 382
Bacterial retention properties of heat and moisture exchange filters 382
Propofol and alfentanil mixture.......................... 382
Different rates of injection of propofol 383
Subdural catheterization and cord damage............... 384
Frequency of damaged coaxial breathing systems........ 384

BOOK REVIEWS

Hyperalgesia and Allodynia 385
Medical Writing: A Prescription for Clarity................ 385
Anaesthesia Review 385

APRIL

EDITORIAL: Extradural abscess after central neural block 387
J. A. W. Wildsmith

ORIGINAL ARTICLES

Closed-loop feedback controlled administration of alfentanil during alfentanil–nitrous oxide anaesthesia 389
H. Schwilden and H. Stoeckel

Comparison of the effect of EMLA cream, subcutaneous ring anaesthesia and a double cuff technique in the prevention of tourniquet pain 394
Y.-C. Tsai, Y.-Y. Lai and C.-L. Chang

Comparison of *in vitro* contracture testing with ryanodine, halothane and caffeine in malignant hyperthermia and other neuromuscular disorders 397
P. M. Hopkins, F. R. Ellis and P. J. Halsall

Recoveries of post-tetanic twitch and train-of-four responses after administration of vecuronium with different inhalation anaesthetics and neuroleptanaesthesia... 402
Y. Saitoh, H. Toyooka and K. Amaha

Prejunctional action of neostigmine on mouse neuromuscular preparations.................................. 405
M. F. M. Braga, E. G. Rowan, A. L. Harvey and W. C. Bowman

An alternative method of increasing $P\text{CO}_2$ using apnoea and continuous positive airway pressure 411
R. Karlsten and S. Englesson

Ventilatory effects of morphine, pethidine and methadone in children................................ 414
K. Hamunen

Comparison of midazolam with propofol for sedation in outpatient bronchoscopy 419
M. Crawford, J. Pollock, K. Anderson, R. J. Glavin, D. MacIntyre and D. Vernon

Comparison of infusion rates of three i.v. anaesthetic agents for induction in elderly patients 423
M. C. Berthoud, G. A. McLaughlan, I. J. Broome, P. D. Henderson, J. E. Peacock and C. S. Reilly

Haemodynamic changes produced by inhalation anaesthetics in the presence of phosphodiesterase inhibition 428
G. Molter, R. Larsen, U. Peters, U. Bauch and R. Sefrin

REVIEW ARTICLE

The value of pre-emptive analgesia in the treatment of postoperative pain 434
J. B. Dahl and H. Kehlet

SHORT COMMUNICATIONS

Comparison of nasal cannulae with face mask for oxygen administration to postoperative patients 440
K. M. Nolan, J. A. Winyard and D. R. Goldhill

Relationship between volume of distribution of atracurium and body weight 443
C. J. R. Parker and J. M. Hunter

Pipecuronium-induced prolongation of vecuronium neuromuscular block 446
I. Smith and P. F. White

Effect of radiant heat on the metabolic coat of postoperative shivering 449
A. Sharkey, R. H. Gulden, J. M. Lipton and A. H. Giesecke

Metabolic effects of propofol and flunitrazepam given for sedation after aortic surgery 451
F. Moritz, J. Petit, N. Kaeffer, G. Oksenhendler, H. Papion, B. Hecketsweiler, N. Moore and C. Winckler

Hepatic elimination of diazepam: interactions with albumin, desflurane and sevoflurane 454
O. Dale, E. J. Frink, L. Thommesen and A. J. Gandolfi

Anaesthetic properties of dimethylthiourea 456
D. D. Koblin, M. J. Laster and J. Liu

CASE REPORTS

Spontaneous excitatory movements during recovery from propofol anaesthesia in an infant: EEG evaluation 459
A. Borgeat, O. H. G. Wilder-Smith, P. A. Despland and P. Ravussin

A continuous subdural block 462
C. B. Collier, S. P. Gatt and S. M. Lockley

Possible venous air embolism with a new water jet dissector 466
J. A. S. Smith

APPARATUS

Fresh gas requirements of an enclosed afferent reservoir breathing system in anaesthetized, spontaneously breathing adults 468
J. R. Barrie, P. C. W. Beatty, I. T. Campbell, G. Meakin and T. E. J. Healy

COMMENTARY

Spinal extradural abscess: pursuit of vigilance 471
P. R. Bromage

ABSTRACTS

Proceedings of the Anaesthetic Research Society, London Meeting, November 20–21, 1992 .... 474P

CORRESPONDENCE

Lumbovertebral syndrome after extradural blood patch . 489
Intermittent *vs* continuous extradural infusion of bupivacaine during labour 490
Does etomidate cause haemolysis? 490
Xylometazoline and porphyria 491
Transthoracic endoscopic sympathectomy 491
Perioperative blood loss 492
Pre-emptive extradural analgesia 493
Metabolic effects of cholecystectomy 493

BOOK REVIEWS

ABC of Transfusion, 2nd Edn 495

Erratum 494

MAY

EDITORIAL: Double-lumen tubes 497
R. S. Vaughan

ORIGINAL ARTICLES

Continuous spirometry for detection of double-lumen endobronchial tube displacement 499
G. I. Bardoczky, M. Levarlet, E. Engelman and P. deFrancquen

Patient-controlled extradural analgesia to compare bupivacaine, fentanyl and bupivacaine with fentanyl in the treatment of postoperative pain 503
D. W. Cooper and G. Turner

Efficacy of continuous intercostal bupivacaine for pain relief after thoracotomy 508
C. M. Dryden, I. McMenemin and D. J. R. Duthie

Morphine-6-glucuronide disposition in renal impairment 511
M. H. Hanna, F. D'Costa, S. J. Peat, C. Fung, N. Venkat, T. R. Zilkha and S. Davies

Partial reversal of the effects of extradural clonidine by oral yohimbine in postoperative patients 515
N. Liu, F. Bonnet, L. Delaunay, N. Kermarec and G. D'Honneur

The pressor response to venous cannulation: attenuation by prior infiltration with local anaesthetic 519
B. T. Langham and D. A. Harrison

Surfactant and adult respiratory distress syndrome 522
W. Jacobson, G. R. Park, T. Saich and J. Holcroft

Penetration of an aerosol, produced by film atomization, through the carinal bifurcation 527
T. J. J. Inglis, J. G. Jones and S. Paxton

Effect of hyperoxia on the breathing of patients anaesthetized with infusions of propofol 532
A. C. Dow and N. W. Goodman

Effects of active and passive sighs in normoxia and hyperoxia on the breathing of patients anaesthetized with infusions of propofol 536
N. W. Goodman and A. C. Dow

I.v. anaesthesia with propofol using a target-controlled infusion system: comparison with inhalation anaesthesia for general surgical procedures in children ... 542
E. Doyle, W. McFadzean and N. S. Morton

Pharmacokinetics of propofol administered by infusion in dogs undergoing surgery 546
A. Nolan and J. Reid

In vivo determination of concentration–effect curves of local anaesthetics in man 552
R. Wiesemes, W. Klement, G. E. K. Novotny and P. Lipfert

I.v. bolus administration of subconvulsive doses of lignocaine to conscious sheep: relationships between myocardial pharmacokinetics and pharmacodynamics. 556
Y. F. Huang, R. N. Upton and W. B. Runciman

REVIEW ARTICLE

The management of acute poisoning 562
G. G. Collee and G. C. Hanson

SHORT COMMUNICATIONS

Effect of age on the sensitivity of upper airway reflexes . 574
R. J. Erskine, P. J. Murphy, J. A. Langton and G. Smith

Endobronchial cuff pressures 576
M. Cobley, J. F. Kidd, B. A. Willis and R. S. Vaughan

Lipid solubility of pancuronium and vecuronium determined by n-octanol/water partitioning 579

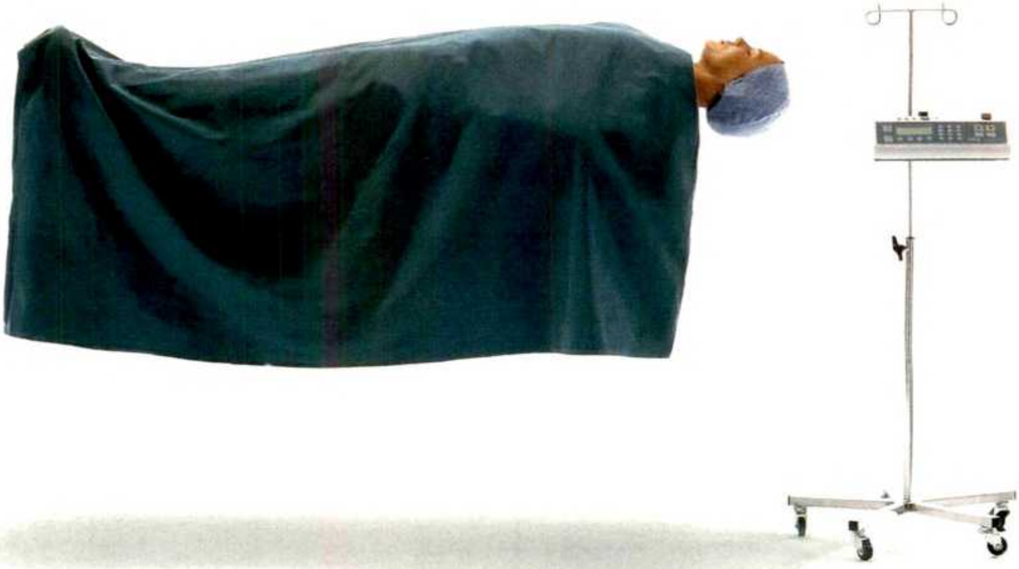
THE ROYAL COLLEGE OF ANAESTHETISTS NEWSLETTER

GOLDEN JUBILEE YEAR

No. 39 March 1998 *Supplement*

ZP117

Diprivan 1%
propofol
MAINTENANCE



Easily controllable anaesthesia[1, 2] and good recovery characteristics[3]
are the hallmarks of maintenance with 'Diprivan'

Diprivan 1%
propofol
MAINTENANCE
Furthering
the art of
anaesthesia

PRESCRIBING NOTES
'DIPRIVAN' 1%
Consult Data Sheet before prescribing.
USE Induction and maintenance of general anaesthesia. Sedation of ventilated patients receiving intensive care for up to three days. Sedation for surgical and diagnostic procedures.
PRESENTATION Ready to use, isotonic, aqueous emulsion containing 10mg/ml propofol in a vehicle containing soybean oil and purified egg phosphatide.
DOSAGE AND ADMINISTRATION Induction: Titrate against response. Adults: Approximately 4ml every 10 seconds in healthy patients and 2ml every 10 seconds in patients of ASA grades 3 and 4. Patients under 55 years are likely to require 1.5 to 2.5mg/kg; older patients generally require less. Children over 8 years: Usually approximately 2.5mg/kg; children 3-8 years may require more. Lower dosage in patients of ASA grades 3 and 4. Children under 3 years: not recommended.
Maintenance: Titrate against response. Adults: Usually 4 to 12mg/kg/hr. Alternatively repeat bolus injections of 25mg to 50mg (2.5 to 5.0ml) may be administered according to clinical need. Children over 3 years: Usually 9 to 15mg/kg/hr. Children under 3 years: not recommended.
Sedation during intensive care: Adults: 0.3 to 4.0mg/kg/hr by continuous infusion. Rates greater than 4mg/kg/hr are not recommended. Take account of other lipids being given. Monitor blood lipid levels of patients at risk of fat overload. Children: not recommended (see Data Sheet).
Sedation for surgical and diagnostic procedures: Adults: 0.5 to 1.0mg/kg over 1 to 5 minutes for onset of sedation. 1.5 to 4.5mg/kg/hr for maintenance of sedation. Bolus administration of 10 to 20mg for rapid increase in depth of sedation. Children: not recommended.
CONTRA-INDICATIONS, WARNINGS, ETC. Contra-indicated in allergy to 'Diprivan' 1%. Not recommended in ECT. Do not use in pregnancy or for obstetric anaesthesia. Should be given only by those trained in anaesthesia or intensive care. Facilities for maintenance of airway, artificial ventilation and oxygen enrichment should be available. 'Diprivan' 1% should not be administered by the person conducting the diagnostic or surgical procedure. Monitor for early signs of hypotension, airway obstruction and oxygen desaturation during sedation. Patients should avoid alcohol before and for 8 hours after administration. Caution when used to sedate patients undergoing procedures where spontaneous movements are undesirable. Extreme caution during bolus administration in acute pulmonary insufficiency or respiratory depression. Concomitant use with CNS depressants, general anaesthetics and narcotic analgesics will accentuate sedative effects. Severe respiratory and cardiovascular depression may occur when combined with parenteral CNS depressants. Caution in cardiac, respiratory, renal or hepatic impairment, in hypovolaemic, elderly or debilitated patients and in disorders of fat metabolism or conditions where lipid emulsions should be used cautiously. Hypotension and transient apnoea may occur during induction. The risk of relative vagal overactivity may be increased, associated with bradycardia and asystole; consider administration of anticholinergic agent before induction or during maintenance when vagal tone is dominant. There may be a risk of convulsion in epileptic patients. Sexual disinhibition may occur during recovery. Safety in breast feeding not established. Ability to drive or operate machinery may be affected. An adequate period is needed prior to discharge to ensure full recovery.
'Diprivan' 1% contains no antimicrobial preservative and supports the growth of microorganisms. Administration must commence without delay after opening the container. Maintain asepsis for 'Diprivan' 1% and all infusion equipment.
'Diprivan' 1% and any equipment is for single use in an individual patient. Discard and replace infusion lines and reservoirs of 'Diprivan' 1% at regular intervals during long-term maintenance or sedation in intensive care. Do not mix prior to administration with other agents or infusion fluids except 5% Dextrose. Do not administer via a microbiological filter.
SIDE EFFECTS Convulsions, myoclonus and opisthotonos may occur (occasionally delayed). Spontaneous movements and pulmonary oedema have been observed. Nausea, vomiting and headache in a small proportion of patients. Rarely, clinical features of anaphylaxis, which may include angioedema, bronchospasm, erythema and hypotension, have been reported with 'Diprivan' 1%. Pain on injection in a proportion of patients. Discolouration of urine and venous sequelae are rare. Post-operative fever has been reported. Minimal evidence of excitation on induction.
LEGAL CATEGORY POM.
PRODUCT LICENCE NUMBER 12619/0010.
BASIC NHS COST £3.88 per 20ml ampoule, £9.70 per 50ml infusion vial, £19.40 per 100ml infusion vial.
'Diprivan' is a trademark, the property of Zeneca Limited.

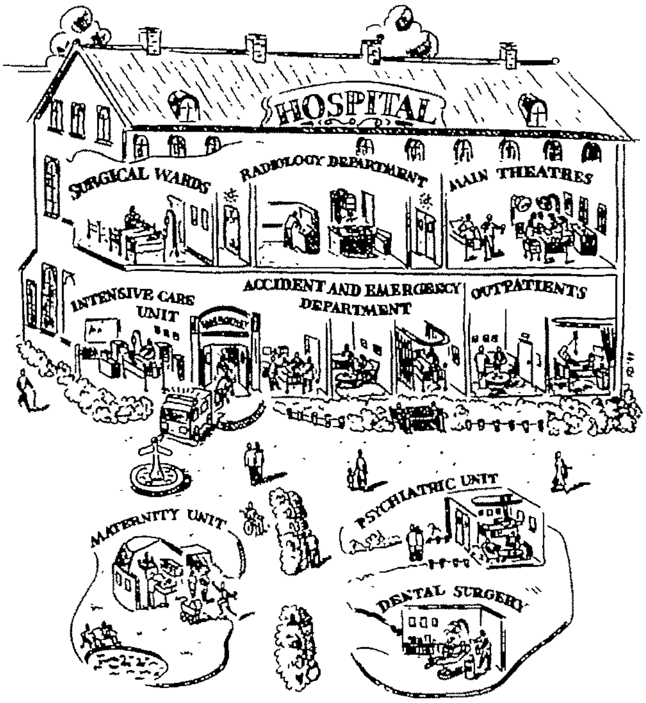
President's Statement

It is a common assumption that the Royal College of Anaesthetists (RCA) has as its primary concern trainee anaesthetists. This is true, but there is also a clear responsibility of the RCA for all others engaged in anaesthetic practice, including the non-consultant and consultant career grades. This way always assumed to be one of the powers of our Royal Charter, but this is not strictly speaking a statutory instrument. However, there are now legal powers laid down for the RCA in the European Specialist Qualifications Medical Order 1995 and the amendments for non-consultant career grade doctors in 1997. Furthermore, the General Medical Council has made it clear in its recent documents that we are all responsible for each other and that the Royal Colleges have a clear role in this matter. In addition, a number of documents have been published and events have occurred recently which impinge on this area of the RCA's interest and influence. These include the White Paper on the National Health Service (NHS), the Audit Commission Report on Anaesthetic Services, and the deliberations of the Specialty Workforce Advisory Group (SWAG - a sub-Committee of the Advisory Group (AGMETS) to the Department of Health) which determines how many SpR posts by specialty there should be in the coming year. This President's Statement will explore some of the interactions of this material, which I hope will be of interest to Fellows and Members.

The Audit Commission Report published in December 1997 is an excellent overview of anaesthesia services (excluding Intensive Care Medicine - the subject of a current review) in the National Health Service. The Report illustrates the pivotal role of anaesthesia in the running of acute service hospitals and contains much material which anaesthetic departments should use to persuade their administrations to improve services to the standard of the best described in the report. The figure from the Report (published with the permission of The Audit Commission) accompanying this article shows in diagrammatic form that anaesthesia pervades all aspects of an acute hospital. Indeed it could form part of a quiz - asking the question "what's missing?" - answer: "the considerable administrative role of anaesthetic departments in day surgery, operating theatres and recovery units, high dependency units, intensive care units and resuscitation services".



One item in the Report which received undue publicity was the impression that there is a shortage of anaesthetists. The Audit Commission did not conduct a manpower survey but conducted a rather biased questionnaire of Chief Executives of Trusts who responded on their past experience when there was difficulty in filling consultant posts. All the evidence we have from our own RCA manpower database and that run by SWAG indicates that over the next four years there will be no shortage of qualified trainees with their CCST ready for consultant posts. Indeed, if consultant expansion is less than 5% per annum (the figure used for prediction of manpower requirements in anaesthesia for the future) there is a risk of overproduction. This would clearly be unsatisfactory. The proposal to extend the SpR period from four years to five (recommended by Council in November 1997 - to begin in January 1999 to accommodate all our training requirements and the proposed further reduction in trainee hours) will help to stem excess production. Nevertheless, we may still need to reduce SpR positions as is currently being recommended by SWAG. The dilemma is that there still are hospitals, including some of our large teaching hospitals, which do not have sufficient consultants and are having great difficulty in fulfilling their service and training requirements. In addition, these are often the very hospitals without the financial resources to advertise consultant posts at a time when there are suitable candidates. Any reduction in SpR positions for these hospitals, without consultant expansion, may be detrimental to the point where they can no longer meet the RCA training requirements. The RCA is engaged in close consultations with the Department of Health as to how these two apparently opposing forces can be reconciled.

The White Paper on the National Health Service commits the service to quality issues. Once way of doing this is the proposal to establish a National Institute for Clinical Excellence (NICE). How this will function is still to be determined. It is of interest, however, that anaesthesia is already considering this matter. Last year all specialties were summoned to a meeting with the Chief Medical Officer to address the problem of outcome studies and improving quality in all specialties. The RCA and the Association of Anaesthetists of Great Britain and Ireland (AAGBI) were asked jointly to put forward a proposal on behalf of anaesthesia for 1998. The exercise is being run by the Joint Consultants Committee (JCC) and the Academy of Medical Royal Colleges (AMRC). The RCA and AAGBI set up a working group Chaired by Dr John Searle which is already well on in its deliberations.

A simple outcome indicator was not thought to be relevant for anaesthesia. Instead the concept of bench marks of good practice we could all agree to, and how to achieve these and how to help those who were having difficulties was thought to be more appropriate. The group is, therefore developing, a "Good Practice Guide for Anaesthesia". It is out intention to hold a meeting of all Clinical Directors in July 1998 to present this Guide in a workshop form. This will be a unique event. At one time and place all those with senior responsibility for NHS anaesthetic services will be able to help the RCA and AAGBI produce a document which all anaesthetists can use to ensure that their practice meets the high standards we all aspire to. In addition, the Guide will be available to all others as evidence of our commitment to quality in our activities.

Anaesthetists sometimes show paranoid tendencies in a belief that nobody knows who we are and what we do or appreciates our contributions to the NHS. I hope that the matters discussed in this statement will go a little way to dispelling these delusions. Make no mistake the senior players in the Department of Health are well aware of the importance of anaesthesia in maintaining the acute sectors of the NHS. The Audit Commission Report has a wealth of material in it illustrating how vital anaesthesia is and it is now up to anaesthetic departments to ensure that as the actual Audit takes place during 1998 they take full advantage to influence their respective Trusts and future "purchasers". For example, by the end of the year every Trust could have an effective postoperative pain service run by anaesthesia; the "Cinderella" of obstetric anaesthesia could be resolved; and the out of hours "emergency work" could be under control. The Audit Commission has provided the tools, it's now up to us to make it happen.

Looking Backwards, Looking Forwards

The foundation of the Faculty of Anaesthetists 50 years ago occurred at a time of enormous change in British Medicine and in Anaesthesia itself. Three years after the end of the Second World War the country was in the throes of widespread nationalisation under a newly elected Labour Government but the country was bankrupt and almost every commodity was rationed and in short supply.

Coinciding with the start of the National Health Service was the end of the era where inhalation anaesthesia with spontaneous breathing was used almost exclusively. Enormous changes were being introduced to anaesthetic practice as a result of the rapidly increasing use of intravenous anaesthesia with thiopentone and neuromuscular blockade with curare. Until that time anaesthetics were administered by an assortment of hospital doctors, general practitioners, dentists and nursing sisters. Even before the 1940's "death on the table" was not a rare complication of general anaesthesia, some practitioners being associated with many more deaths than others. Not only was the specialty suddenly in need of re-invention, there was also an urgent need for the development of an understanding of the dangers of the two new intravenous drugs. The Association of Anaesthetists, already in existence, was one of the bodies that saw the need for a Faculty or College of Anaesthetists to oversee the standards in the specialty. In this issue Professor Cecil Gray describes the foundation and evolution of the Faculty of Anaesthetists.

The 50 years which followed the introduction of the Health Service and Faculty/College of Anaesthetists saw the rapid development of a hardware-orientated specialty. The anaesthetist by and large had to be a mechanically minded person. Most were keen to advance his/her practice by developing the educated hand

Articles and correspondence for inclusion in the May issue should be sent to the Editor (c/o Mrs M J Kelly at the College) by Friday, 20 March 1998.

and inventing all kinds of needles, tubes, connectors airways, masks, vaporisers, ventilators and later blood gas analysers and monitoring equipment. Many of these devices developed in the 1950's and 60's were the results of the efforts of anaesthetists themselves. Some, such as the Manley Ventilator, are still in use in my hospital today. In this issue John Bushman describes some of the work of another innovator James Rochford, and Bill Mapleson outlines some of his own work over most of the last 50 years. In parallel with all these changes were a number of spectacular advances made by pharmaceutical companies. In particular the introduction of new volatile and intravenous anaesthetic agents, opioids as well as a range of muscle relaxants. Against this background the Faculty/College introduced the FFARCS/FRCA examination as well as many courses and became increasingly concerned with standards of anaesthetic training and practice. With all these developments Anaesthesia spawned a number of promising offspring. Particularly notable were intensive care and chronic pain therapy. Both subspecialties began tackling problems in which initially no one else wanted to get involved but now, after much of the heavy spadework has been done by anaesthetists, both seem ripe for cherry picking by other specialties and may split from the parent specialty.

What of the specialty of anaesthesia itself now and in the future? 50 years after the introduction of the National Health Service and of the Faculty/College we again have a new Labour Government with a mandate to tackle seriously difficult national problems but with very limited resources to do so. Thus there are formidable problems to be solved before the demands of the NHS can be met. There is an insatiable appetite for Social Security funding. More than 32% (£100 billion) of the total annual government expenditure goes to Social Security; another 17% to Health and Social Services and 12% to Education. Tax payers do not want to pay more for Health and Social Services. Real growth areas are drug addiction, violent crime, obesity, "dumbing down". Fraud is so widespread that the Department of Health is advertising for a Fraud Supremo to accompany the Drug Czar.

The recent White Paper proposes a "third way" between the old bureaucratic command and control system and the fragmentation and distortions of the internal market. This will be led by primary care groups focused on population health. Anaesthetists could be further marginalised as these groups negotiate directly with Surgeons. One of the themes of the White Paper is the introduction by 2000 of "NHS DIRECT", a 24 hour nurse led telephone helpline. Wide access to interactive sources of information, be they helplines or World Wide Web, clearly empowers potential patients who will increase demands for detailed informed consent for anaesthesia.

The costs of giving an anaesthetic are not high but salary costs are considerably greater than drug costs. Consultant job plans presently have lots of blank spaces – room here for workload expansion? The wide availability of portable telephones and closed circuit television would make the introduction of the supervisory consultant fairly easy, e.g. the American system of one consultant supervising several, less trained, personnel in different operating rooms. Measurements of workload and complexity may form the basis of remuneration but increasing time spent on CME, CPD and simulators may leave nothing left for actual hands-on clinical work.

What of possible new clinical developments? Powerful new analgesics without respiratory side effects would transform the specialty but may create post operative problems in masking surgical complications. Opportunities here for Anaesthetists as peri-operative physicians? Elective transplant surgery will rapidly expand because of advances in transgenic animals and cloning of human organs and tissues. But if a viral stowaway in a Xenotransplant spreads from a recipient to others it could cause pandemics similar to Ebola, Marburg or even HIV (*Nature* 1998. 391. 320-324). Increasing drug addiction and dependence amongst anaesthetists seems likely in the future. Strategies described by Professor Milde in this issue must be developed now to contain this problem. Major advances in the specialty itself seem unlikely, particularly with the departure of intensive care and chronic pain work. At the start of a new millenium, and unlike the 1940's, anaesthesia has the feel of a specialty with a high degree of clinical expertise and safety but it seems to be in an evolutionary cul-de-sac, a constant target for cost cutting and a takeover by other groups. Sustained efforts must be made to ensure that there is a Royal College of Anaesthetists in 50 years time.

J Gareth Jones, Editor.

From the Registrar

I am delighted to be going into print for the first time in post as the College Registrar. I expect that this column will appear regularly in the College's Newsletter and that I will be able to take the opportunity to comment on various events which occur between publications, and in general about the College.

I hope that the design of the Newsletter in our Jubilee Year will bring it to the attention of Fellows, Members and registered trainees, and that they will want to read it and indeed get some enjoyment from it! The College is greatly indebted to ZENECA who continue to fund, with great generosity, the printing of our Newsletter. They have been marvellous benefactors over the years, and continue to be so. GlaxoWellcome have kindly joined forces with us. They are responsible for funding our new colour cover as a celebration of our Jubilee year and they have agreed to give us this continued support. We are grateful to them.

I joined the College in September and part of my remit is to try and improve communication externally. This must include not only Fellows, Members and trainees but also the rest of the medical profession, the NHS, the general public, the press and Government. It is an enormous challenge and I hope that Fellows, Members and trainees have noticed improved communications recently and feel that we are becoming more open, more ready to communicate, and very willing to explain as well as listen. The President and Council certainly wish an open and accessible College for Fellows and Members.

I seem to be the person to whom people come, be they anaesthetists or members of the public and press, to dispel or confirm myths widely held. Perhaps I can repeat a few. The first has received widespread publicity in the free medical press. We are told that there are an unusually high number of Fellows who are not paying their subscription. Let me dispel that myth. There are not. There is a small core of people who do not pay, but on the whole Fellows do pay their subscription and recognise its importance. There is one very good reason to pay. It is the College's responsibility to set and maintain standards. We are independent of Government and so we should be. If we are not funded by our own Fellows, then we will lose that independence, something I think most doctors would find more abhorrent than paying a subscription.

What about also dispelling a myth for trainees? After the recent exams held at the College, I am told that one of the common myths is that we have a quota of passes at the Final examination. This is not, and has never been, the case. How do we best allow exam candidates to know this, and in a way that we will be believed? I expect the increasing popularity of observer status at the exams will result in those observers returning to their departments to say what really does go on.

For one reason or another none of the Colleges appear to be wallowing in popularity at the moment. There is no doubt that as a College we do need to be proactive, we need to have an agenda, we need to have targets which we are trying to achieve, and we need to let our Fellows, Members and registered trainees know what these are.

I am currently planning a series of roadshows across the country so that the President, Chief Executive and myself can provide a forum for information exchange and discussion of College policy and local issues. We hope to have our first visit around April and will be asking for invitations to visit centres across the UK later in the year. I hope that we will be welcome and that the meetings can be used in a constructive way to bring us all together for the good of our specialty and for our patients. I would be interested to know who might consider inviting us?

Thanks to the contribution of many Fellows we have improved the immediacy and the appropriateness of our Newsletter. We have also created a College website and are excited by the potential for the spread of information in this way. The RCA website went live on 2 Janaury 1998. We have started off with information about the examinations, the College and its history. We will be expanding soon, Dr Peter Simpson from Bristol and member of Council, has been appointed as Editor. Patience is needed in this area. You all must appreciate the importance of accuracy of any documents put on the website. You can access the new Royal College of Anaesthetists website by using the address: **http://www.rcoa.ac.uk.**

There is no doubt that a correspondence column can enliven and enlighten any publication. The Newsletter is no exception. I hope that you will be provoked into writing, not only about what you see in this publication but also your comments on general issues relevant to anaesthetists which appear in other magazines which drop onto our doorsteps. This is a Newsletter for all Fellows, Members and registered trainees. We need you to contribute as much as you need us to communicate.

Juliet M Davies, Registrar.

The Evolution of the Faculty of Anaesthetists of the Royal College of Surgeons

by Professor T Cecil Gray, Past Dean, Faculty of Anaesthetists.

Before reviewing the foundation of the Faculty of Anaesthetists, it is necessary to summarise the evolution of the specialty in this country from the earliest days. From the London Society of Anaesthetists developed the Section of Anaesthesia in the Royal Society of Medicine. The offspring of the Section was the Association of Anaesthetists of Great Britain and Ireland, which, in 1932 stimulated the Conjoint Board of the Royal Colleges of Physicians and Surgeons to institute the first Diploma in Anaesthesia in the world.

The two major wars were important stimuli to the advancing specialty. The Great War "to end all wars", resulted in the evolution of the Boyle's anaesthetic "machine" and the Magill endotracheal tube. The 2nd World War produced large numbers of young General Practitioners, who, in the Forces, gained considerable experience in anaesthesia, many of them picking up a Diploma in Anaesthesia on the way. Then came neuromuscular block demanding obligatory advanced training in physics, physiology and pharmacology and last, but by no means least, the National Health Service instituted in 1948 made it possible for that ex-service body of anaesthetists to obtain specialist employment.

Before the 1939 war in the hospitals of this country, anaesthetics for surgical sessions, by and large, were administered by general practitioners and lady doctors, some married to surgeons and others who also did "clinics": in out-patient departments and at night it was left to the house surgeons: only very occasionally for a desperate or private case, would a surgeon call out his best anaesthetist. The late Ivan Magill used to tell how, after qualification, his first house job was at the Stanley Hospital in Liverpool where he was told by the surgeons that he was to give the anaesthetics - although his only training had been the usual twenty anaesthetics administered during his student days and he doubted whether he had completed those. In the event, he was so good at it that he became their favourite anaesthetist. It must be difficult for today's anaesthetists to appreciate the situation in the pre-war specialty. Up to the 1939 war, theatre uniform was worn only by the surgeons: in the operating theatre, anaesthetists usually wore their ordinary clothes simply covered by a white coat or theatre gown and a cap with or sometimes without a mask. There were in each large centre a very few full-time anaesthetists. Most of the distinguished anaesthetists of that time who held office in the Royal Society's Section of Anaesthesia and in the Association of Anaesthetists and most of the examiners for the DA, were still involved in general practice, which was the only sure way to earn a decent living.

Came the war and in 1948, the NHS was introduced, those who had passed the DA obtained full-time posts, the younger and less experienced finding junior hospital posts in which to get further training.

Only three medical Royal Colleges existed at that time - those of Physicians, of Surgeons and of Obstetricians and Gynaecologists. Fortunately, the RCP and the RCS had Presidents who were wise and far seeing and were much concerned in the planning of the NHS. The President of the RCP, Sir Charles McMoran Wilson (later becoming Lord Moran) was Honorary Consultant to St Mary's Hospital, Paddington: he was a strong and crafty man who dealt firmly with the BMA's reluctance to allow the Royal Colleges a major voice in the planning of the NHS. The President of the RCS handled the BMA a little better remaining friendly with its Secretary, Dr Hill, who was something of a bete noir to Moran. Perhaps this was a small factor in determining the status of anaesthesia in the Service.

The President of the Royal College of Surgeons was Sir (later "Lord") Alfred Webb-Johnson, Dean of the Middlesex Hospital; he was referred to by all his friends as Webb-J. With other far-seeing members of his Council, he appreciated that surgery was advancing rapidly and would continue so to do and, if that advance were to continue, they realised that there would have to be advances in anaesthesia and in the status of that specialty.

Webb-J's anaesthetist at the Middlesex Hospital was Dr Bernard Richard Millar Johnson, the Honorary Treasurer of the Association of Anaesthetists (1947-50). They were close friends and shared a special interest in the Army - Webb-J had been Chairman of the Army Medical Board during the war and Bernard Johnson - Johnny to his friends - had served in India and, after the war, he became the Honorary Civilian Adviser to the Army. There is no doubt that the future of anaesthesia in the post-war world would have been a frequent subject for discussion by this surgeon and his anaesthetist, as indeed it was for most of us.

Bernard Johnson was clever, dedicated and ambitious. He demanded from himself and his trainees the highest standards in both work and behaviour and, incidentally - amazing as it may seem today - he was one of the few anaesthetists who insisted on doing ward rounds to see his patients the day before their operation. Johnson longed and would do his best to see changes in the standing of anaesthesia and its practitioners.

As early as 1946, the Royal College of Surgeons had decided to build a Residence for Fellows onto the College with accommodation for department in the basic sciences: endowed by Lord Nuffield, it was built and became the Nuffield College. Web-J was keen to introduce into the College clinical disciplines allied to surgery and saw that a way of doing this would be to have "Faculties". Faculties would not only raise the status of their specialties, but would also increase the number of Fellows in the College, which, incidentally, would not be detrimental to its financial well being.

The concept of Faculties was readily accepted by the Council of the College and was very quickly implemented by the creation of a Faculty of Dental Surgery.

Of course, Webb-J would have told Bernard Johnson about this development and one can almost hear Johnson exclaiming "What about anaesthesia? What about a Faculty of Anaesthetists?" However, Webb-J's interest in having another Faculty in the College was such that it may well have been he who made the suggestion.

However that may be, it is most likely that it would be Johnson who suggested a meeting of Webb-J with the President of the Association of Anaesthetists, Dr Archie Marston, senior anaesthetist at St Mary's Hospital. They probably already knew each other through the RSM or other societies. They met and subsequently Webb-J proposed to the Council of his College that Marston should be co-opted to the Council. Such co-option of an outsider, I think, was then without precedent. That Marston's co-option was readily accepted was evidence of the commanding influence of the President, for, in those days, it is likely that there would be quite a few Council members who would look askance at a suggestion to co-opt an anaesthetist. However, some would be enthusiastic and principal among them would be Sir Henry Souttar of the London Hospital, who, incidentally, had taken over from Webb-J the Chairmanship of the Army Medical Council. Souttar was to become an ardent supporter of the Faculty and did everything he could to encourage it in the Council of the College.

Marston invited Webb-J to address the Council of the Association which he did, on 11 April 1947. He showed considerable enthusiasm for up-grading the specialty, but he was seriously concerned as to the academic standard of the Diploma in Anaesthetics (DA) as compared with a Fellowship in a Royal College. He pointed out that there was little chance of anaesthetists achieving consultant status in the NHS unless their qualification could be seen to be comparable to the two-part Fellowship examination in surgery and he stressed that this equality could only be achieved if anaesthetists *"were to continue their wartime interests outside the operating theatre in peace-time, in such areas as pre- and post-operative care, resuscitation, blood transfusion and oxygen therapy"*.* The DA was obviously inadequate, but, he suggested, if a Primary Examination in the basic sciences were introduced, it would upgrade the examination and successful candidates in both parts would be eligible for a Fellowship as would those senior anaesthetists who would be recognised for their contribution to the specialty. Time was short and this would be the quickest way to prepare for a Faculty.

The Association accepted these suggestions: the Conjoint Board of the RCP and RCS which was responsible for the DA examination were consulted and agreed to the proposed alteration in the regulations.

At the AGM of the Association of Anaesthetists held on 30 October 1948, the new regulations were accepted and the first two-part DA examination was held in November 1948. Upgrading of the examination was agreed on a vote, but there were members of Council of the Association who were sceptical about a Faculty seeing it as a threat to both the Association's educational activities and their control of the standard of the examination. However, negotiations with the Royal College were continued and it was obviously advisable to consult the Fellows (there was such a grade in those days) and Members of the Association. A Special General Meeting in London was called for 6 February 1948.

At that meeting the new President of the Association, Dr John Gilles of Edinburgh took the Chair.

---

* The italics are mine: for these words and details of Webb-J's address, I am grateful to Dr T B Boulton who allowed me to peruse pages from his forthcoming "History of the Association of Great Britain and Ireland". It saved many trips to London!

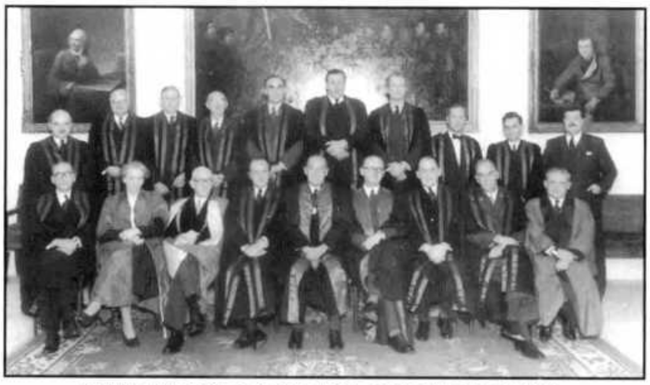
I was present and remember that meeting vividly - so very much was at stake. I strongly favoured a Faculty and as the discussion proceeded I became more and more apprehensive.

Marston, the past President, was the first speaker and put the proposition firmly: these are not his words but they indicate the spirit of his speech as I remember it. He warned of a dire future for the specialty if there were failure to take what would certainly be a very great step forward. Failure to grasp this opportunity would result in anaesthetists being second class citizens in the new NHS and ineligible for the position of consultant. He announced the establishment of the two-part DA examination, but stressed that even such a diploma alone would not provide the prestige of a Fellowship in a Royal College and recruitment to the specialty was likely to be very difficult.

The Founder of the Association, Dr Featherstone of Birmingham, Dr Langton Hewer, the Editor of the Associations' Journal and Dr Mennell, the Honorary Treasurer of the Association, expressed fears that the Association would be downgraded and would lose out, no longer having any control over the examination, its standard and the nomination of examiners. This was an understandable reaction from those who had been around when the Association was founded, but there was no doubt in the minds of the ex-servicemen present. They had become accustomed to having equality of rank and remuneration with their surgical and medical colleagues and were not inclined to see that change. Eventually, all was well. The greatly esteemed Dr George Edwards, Senior Anaesthetist of St George's Hospital, who had been Brigadier in charge of anaesthesia with the first army in North Africa, moved the motion "That this meeting is in favour of the proposal that the Association of Anaesthetists should apply for the formation of a Faculty of Anaesthesia within the Royal College of Surgeons of England". It was seconded by Bernard Johnson, also ex-service, with a full spirited, indeed very slightly aggressive speech and the motion was passed nem con. The result of this meeting was that the College quickly established the Faculty of Anaesthetists.

Who chose the members of the Foundation Board of the Faculty (figure 1), I have forgotten, but I can suggest with considerable confidence that it would be Marston and Johnson who made the decisions, almost certainly assisted by the President of the Association, Dr John Gilles. I was genuinely shocked when, one evening shortly after that crucial meeting, I was rung up by Bernard Johnson asking if I would serve on the Board of Faculty. I suspect that my friend, Dr Vernon Hall, the only other surviving Foundation Fellow, may have been equally surprised, although his nomination was certainly more to be expected than mine. There was no hesitation in my reply. In the event, Professor Edgar Pask, Dr Ronald Woolmer and I were to represent the "Members" of the Faculty who would be those who were not elected to the Fellowship but who were practising full-time anaesthesia with a one-part DA.

The first meeting of the Board of Faculty was held in the Library of the Royal College of Surgeons. One of its first tasks was to elect a Dean and Vice-Dean: not surprisingly Archie Marston was elected Dean and Bernard Johnson Vice-Dean. The next important task was to elect foundation Fellows.



THE FIRST BOARD OF FACULTY

Back Row (from left to right): Dr T C Gray, Dr F T Evans, Dr V F Hall, Dr B L S Murtagh, Dr A H Musgrove, Dr W A Low, Dr R F Woolmer, Dr G S W Organe, Professor F A Pask, Mr W F Davis *(Secretary)*

Front Row (from left to right): Dr J H T Challis, Dr K G Lloyd-Williams, Dr E S Rowbotham, Dr B Johnson *(Vice-Dean)*, Mr A D Marston *(Dean)*, Dr I W Magill, Dr G Edwards, Dr C Langton Hewer, Dr R E Pleasance

Obviously, the nominated Board had to agree to elect themselves and they included the three who represented the members. The election of foundation Fellows of the Faculty took several meetings and I remember the Dean observing that, in choosing foundation Fellows, we had to be generous so as to ensure that with the two-part diploma should be given a Fellowship and also those with the one-part diploma who had distinguished themselves in anaesthesia or had given long and recognisably valuable service to the specialty. A few senior anaesthetists, without a DA, but with a good local reputation, were also accepted for the Fellowship.

Thus was the Faculty of Anaesthetists launched and its Fellows can look back with some pride on its achievements over the nearly fifty years. They have justified the optimism of its founders and the remarkable success of the Faculty's Fellowship transformed a Cinderella specialty into one in the front line by ensuring that its Fellows had the skill, experience and knowledge to advance anaesthesia and the enterprise to form branch sub-specialties of Paediatric and Obstetrical Anaesthesia and also, one badly needed, Pain Management.

The climactic final achievement has been the rise of an independent Royal College of Anaesthetists without rancour in the parent College. The debt that this new Royal College owes to the Faculty and its inspirational founders, Lord Alfred Webb-Johnson and Dr Archibald Marston, should never be forgotten.

It has been a great pleasure to recall and pay tribute to those who launched such a remarkable and successful ship.

A Physicist in Anaesthesia

by Professor W W Mapleson, Professor Emeritus of the Physics of Anaesthesia, University of Wales College of Medicine, Cardiff.

I became involved in anaesthetics when I was nearing the end of my PhD, on "Point Discharge in Atmospheric Electricity", in 1952 in Durham. I saw an advert which read "Wanted in the Anaesthetics Department in Cardiff, someone with a wide knowledge of physics, physiology or pharmacology". I decided that this would give me some useful interviewing experience. To my acute embarrassment I was offered the job and I was faced with making a decision. So I said to the Head of the Department, Dr Mushin as he then was, that I would like a day or two to think it over. I think he was a bit taken aback by this because it wasn't the sort of thing anyone said to Mushin. I decided to accept, on the basis that "it would do for five years". In fact the relationship with anaesthesia has so far lasted for forty-five years.

When I joined the Department, in October 1952, it was in the Cardiff Royal Infirmary. The staff consisted of William W. Mushin; his secretary, Muriel Fairweather; a technician, Ken Hillard; and a records secretary. In addition, all the clinical anaesthetists were regarded as members of the Department. Mine was the first non-medical academic appointment in the Welsh National School of Medicine (now the College of Medicine) in Cardiff, and it is a tribute to Professor Mushin that he foresaw the contribution which basic scientists can make to the development of medicine. This is now widely accepted, but 50 years ago it was revolutionary.

The department then had a well-equipped mechanical workshop and a laboratory which contained benches and cupboards but little equipment beyond some glassware and a bunsen burner. My first assignment was to make measurements of the muscle relaxation produced by gallamine triethiodide (Flaxedil) which was the first synthetic muscle relaxant. For this project, Professor Mushin had obtained a grant of £250 from the Association of Anaesthetists to buy a nerve stimulator; but I convinced him that, with "that amount of money", I could equip the department for electronics and build our own stimulator. Mushin specified that we should stimulate the ulnar nerve at the wrist and record the force of the contraction of the short muscles of the thumb. Ken Hillard constructed the force-measuring equipment and I constructed the stimulator. Both were state of the art: the recording system used a hot wire moving over heat-sensitive paper instead of the then-standard smoked drum; the stimulator incorporated pulse techniques which I had learnt during my two years of National Service in the RAF.

We decided that the measurements should be made in conscious volunteers to avoid the extraneous movements that would be inevitable in theatre. While supramaximal stimuli are considered essential to ensure return to baseline when the relaxant has worn off, I felt that, to obtain an adequate supply of volunteers (all members of the Department) we would have to use submaximal stimuli. I thought that stability of contraction would be achieved by controlling, not the voltage applied to the stimulating electrode, but the current through it. This proved inadequate but the problem was eventually solved with the "multi-wick electrode". This comprised five narrow electrodes, ranged side by side, with an equal controlled current through each. The aim was to produce a uniform current density across the wrist, so that relative movement of nerve and electrode would not alter the number of nerve fibres stimulated. And it worked! To quote the published paper: the contraction strength at the end of an experiment "rarely deviated by more than 5%" from baseline. The eventual publication was also innovative in that it included some pharmacokinetic modelling of the results, laboriously worked out on an electro-mechanical calculator. The volume of Anaesthesia in which the publication appeared, in 1955, contained an advertisement for Flaxedil, but it also had one for "Macfarlan's Anaesthetic Ether" and, not unconnected with the latter, one for the Baldwin "Statigun" to detect static charges. Happily, explosions are no longer "the constant worry of the anaesthetist"!

While I was waiting for suitable volunteers I began a little pot-boiler on breathing systems. Professor Mushin had drawn out five semi-closed systems and said "Have a look at these and see if you can work out what is required to eliminate rebreathing. There is a chap called Molyneux in Newcastle who has analysed the first one, but I'm not sure if he has got it right and no one has looked at the others". Mushin told me nothing about the systems, but I needed some means of referring to them so I just labelled them A, B, C, D and E. I was astonished to find that, within two or three years of publication (in 1954 - before the gallamine paper) they were being referred to as the "Mapleson A", "Mapleson B" and so on. Thus are reputations made! It was generous of Mushin to allow me to publish the paper just in my own name. However, I would like to take this opportunity of apologising to Dr Jackson Rees and, posthumously, to Sir Ivan Magill for not acknowledging them as the creators of systems "D" (strictly, the later "F") and "A" respectively.

My main research interest over the years has been the uptake and distribution of anaesthetics. My first mathematical model of the uptake and distribution of an inhaled anaesthetic took the form of a network of capacitors and resistors - a "passive" electric analogue computer. Having had the idea, I discovered that the technique had been used in other fields - where physicists had worked with clinicians - but Cardiff was the first Department to apply it to anaesthesia. I demonstrated the analogue at a meeting of the Anaesthetic Research Society (then the Anaesthetic Research Group) in 1960, showed a film of it at a biophysics congress in Stockholm in 1961, and even took the computer, assembled in a purpose-built attaché case (constructed by Ken Hillard), to New York for the conference on the "Uptake and Distribution of Anaesthetic Agents". There I was able to use the computer to make additional calculations between the first and second days of the conference - shades of the modern laptop computer!

That conference was a nice demonstration of the fact that there is a right time for an invention: two other electric analogues of uptake and distribution were reported, and Ted Eger presented the first digital computer model. While waiting for a digital computer service to become available in Cardiff, we made good use of the electric analogue. In 1963 we programmed it for the newly available methoxyflurane to predict how that very-high-solubility agent might behave clinically. We demonstrated it at the Anaesthetic Research Society meeting in Cardiff that year and I remember Alex Forester, then head of the Anaesthetics Department in Glasgow, cautiously giving his first methoxyflurane anaesthetic to the analogue - a forerunner of present-day patient simulators.

Since then, other computer-program models have been written in the Department: in Fortran (by Peter Allott), in BBC Basic, and in the form of a spreadsheet (by Valerie Flook, one of my first two research assistants, who is currently using it to calculate safe decompression procedures in deep-sea diving). The most interesting version was written in the 1980s by Norman Davis as part of his PhD project. This was a detailed physiological model for injected agents which we considered required the separate representation of all forms of the drug: ionised and unionised dissolved in water, dissolved in lipid, and bound to protein.

A logical development of a computer model of pharmacokinetics is to use it to control the administration of an anaesthetic or, to put it more tactfully, to assist the anaesthetist in the control of anaesthesia. Our first attempt in the early 1970s was before the days of on-line computers, so the running calculations for control were done by four physicists, (Peter Allott, Bob Chilcoat, Brian Willis and myself) each with an electronic calculator one of which actually had four memories and a square-root key! Alan Steward, a physiologist cum pharmacologist, was responsible for the overall running of the project.

A subject which is inextricably linked with uptake and distribution is the use of low fresh-gas flows in inhalational anaesthesia. In fact it was the need to tackle this problem, when that "new, expensive anaesthetic" halothane was introduced in 1957, that stimulated my interest in uptake and distribution. Subsequently, each time another "expensive" anaesthetic was introduced, I was asked to talk about its use with low flow, either just to the Department, or at the Warsaw European Congress in 1990, or at the Edinburgh ALFA symposium in 1996. This last was the first to address the problem of how to control the fresh-gas flow and concentration in the first few minutes of anaesthesia instead of the much simpler problem of how to do so once a steady state has been achieved. It has recently appeared in anaesthesia.

An enduring interest of Professor Mushin's which I shared was lung ventilators. Together with Leslie Rendell-Baker and Peter Thompson, this culminated in the book "Automatic Ventilation of the Lungs", which ran to three editions and which John Lunn irreverently dubbed "The Puffing Bible". My contribution was in analysing the relationship between the mechanical construction and the resulting waveforms of flow and pressure produced in the patient's respiratory system. Curiously, there is little agreement on the "best" waveform. The subject is bedevilled by the many mathematical connections between the different variables. Our approach (that is, John Lunn, Bob Chilcoat and myself) was to vary frequency, tidal volume and inspired oxygen concentration in such a way as to maintain constant levels of mean airway pressure and of arterial tensions of CO2 and oxygen. We showed that wide changes of frequency then had no important effect on physiological dead space, cardiac output or venous admixture. On the other hand, recent work by John Mecklenburgh for his PhD, which I supervised, suggests that when the ventilator is merely assisting the breathing of a conscious subject, waveform of flow or pressure may indeed be important, and even that different subjects may prefer different waveforms.

My 45 years in the Department have now spanned three Heads of Department. With Professor Mushin, since he appointed me in the first place as a raw not-quite-PhD researcher, it was inevitable that our relationship would always remain in some degree, and in the nicest possible way, that of the iminence grise and the young newcomer. Thus he played a major part in determining what projects I worked on, although he then allowed me free rein in how I pursued them - with the regular discussions that need to go on for any research project to be successful. When Professor Michael Vickers arrived, I was already something of an authority on some subjects, and I had my personal chair. Therefore our relationship was nearer to that of Mike being "first among equals". So I had a freer rein. Apart from supervising, or co-supervising, a series of PhD theses (those of Bob Chilcoat, Norman Davis, Couto da Silva, John Mecklenburgh and Takashi Asai) I found myself becoming involved in any mathematical or statistical aspects of clinical projects in the Department - but always, as with Bill Mushin, with frequent discussions with Mike Vickers of planning and progress. My work was evidently appreciated by Mike because, when I retired in 1991, he arranged for me to have a formal half-day-a-week consultancy for the benefit of young researchers in the Department. This has continued very amicably under our new head of department, Professor Michael Harmer, and has provided me with a steady stream of new problems to be solved. Together with writing up projects that were incomplete at the time of retirement, and requests for help from various Departments outside Cardiff, I find myself still working a 40-hour week. The main difference is that most of the time I now work at home, with a pleasant view of the hills behind Cardiff, instead of looking out on the blank concrete wall of the operating-theatre block.

My first association with the College, then the Faculty, was in 1963 when I was asked to lecture on "The Uptake and Elimination of Inhalational Anaesthetics" on the "Course on Anaesthetics". I continued to lecture on that subject on every such course until January 1996, and for many of those years I also lectured on Anaesthetic Breathing Systems. Mushin always insisted that no pains should be spared to make every publication and every lecture as clear and as simply expressed as possible, and the main tool for achieving this in the uptake lectures has been the water analogue. My notes for that first lecture include a primitive form of the analogue which I suspect I devised expressly for the occasion. Over the years I have progressively developed the analogue, eventually finding a satisfactory means of incorporating the concentration and second-gas effects in 1987. For the breathing-system lectures, the main tool was animated overhead projection, a technique I developed after seeing Peter Armitage the statistician use it in a lecture at the RSM.

The College honoured me with the Faculty Medal in 1981, the Dudley Buxton medal in 1992 and, what I prize most, Honorary Fellowship in June 1996. I hope that I shall continue to cerebrate adequately to contribute to anaesthesia for a few more years yet.

This is an edited version of a similar article published in "Essays on the First 50 Years 1947-97" Edited Appadurai IR and Horton JN Department of Anaesthetics, University of Wales College of Medicine, Cardiff. Blackwells 1997.

Royal College of Anaesthetists Newsletter March 1998, Issue No. 39

Drug Dependence Among Anaesthetists in the United States

by Professor L N Milde, Chairman, Department of Anaesthesiology
Mayo Clinic, Arizona, USA.

Introduction

In a society where increasing numbers of people are becoming dependent on drugs it is not surprising that a minority of doctors cannot avoid the self-use of drugs with which they treat their patients. Although the first self-use of drugs may be difficult to explain, subsequent chemical dependence (drug addiction) is recognised in the United States as a chronic progressive disease which is characterised by compulsion, the loss of control over drug use, and continued use despite adverse consequences. It is associated with stress, a lack of a constructive outlet for stress, a willingness to experiment with the self use of drugs, and a belief that physicians are invulnerable and can control their own drug use. The easy access to potent drugs by anaesthetists is a contributory factor. Abuse of drugs by physicians is more common than dependence. Some abuse drugs "recreationally" to feel better, others self-medicate to relieve illness or stress. The use of alcohol typically takes years to become dependent while dependence to sufentanil occurs almost after the first use.[1]

Policy For Managing Chemical Dependence

Chemical dependence is the most common occupational hazard within the speciality of anaesthesia in the USA.[2345] In 1986 the American Society of Anaesthesiology (ASA) produced a statement that "it is important that anaesthesia departments have mechanisms in place before a problem develops so that when realistic concerns or reasonable evidence for drug or alcohol abuse surface, appropriate, rapid, and safe action can be taken". The (ASA) produced a paper entitled *Chemical Dependence Guidelines of Departments of Anaesthesiology.*[6] It offers both a plan for education about chemical dependence and a plan for action including a sample chemical dependence policy. This states that:

1. Chemical dependence is a disease.
2. Untreated or relapsing chemical dependence is incompatible with the safe clinical performance in anaesthesia.
3. It is the duty of all members of the department to share their concerns about chemical dependence ... with a designated resource person.
4. Any member of the department suffering from active chemical dependence shall immediately be placed on leave of absence.
5. Return from medical leave for chemical dependence shall be governed by the departmental re-entry policy.

The Chemical Dependence re-entry Policy of the ASA states that:

1. Leave for treatment of dependence shall be recorded in the member's personnel file and shall be released only upon the written permission of that member.
2. If the Head of Anaesthesia, in consultation with a specialist in chemical dependence, determines that the performance of anaesthesia by a member is impaired due to chemical dependence, then the member must resign from the department.
3. If as in (2) it is determined that the performance of anaesthesia is compatible with recovery from chemical dependence, the member shall sign a re-entry contract before being granted staff privileges.

The ASA guidelines for a re-entry contract include:

1. An actual contract should be drafted by legal counsel.
2. The treating physician must be qualified to treat chemical dependence.
3. The recommendations of the treating physician must be followed including aftercare programs and continued abstinence from substances of abuse.
4. The member must agree to random blood/urine tests screening for drugs
5. All medical supervision and drug screening must be done by a physician outside the department of anaesthesia.
6. Violation of this contract (evidence of drug abuse or positive drug screen) results in termination of staff privileges. The department has the option to reinstate staff privileges after further treatment.

In 1991 the ASA reported that the incidence of chemical dependence among anaesthesiologists was 0.7 % / year. Most were residents (87%), male (88%), and most of these were in their first two years of anaesthesia training. Of those that were faculty members (11%) most were young in entry level positions (instructor, assistant professor). A family history of chemical dependence occurred in 32%. Twelve percent joined anaesthesia training programs with a prior history of documented substance abuse. A large percentage were high achievers; most have been in the top or middle third of their medical school class.

Narcotics are the most common substances of abuse among anaesthesiologists with fentanyl being the most common (57%) and sufentanil being next (8%). In this study 48% successfully returned to work but the relapse rate of those returning to work was 21%. There were 12 deaths reported from narcotic use. The overall success rate of a California program[7] was 66% among anaesthesiologists. Of the recovering anaesthesiologists 96% continue to practice in their speciality. This indicates that intensive inpatient treatment and supportive aftercare play an important role in the success of recovery and contradicts the pessimism expressed in an earlier study in which the relapse rate among anaesthesiologists was reported to be 66%.[8] In that study the first sign of relapse was death in 16%. The same relapse rate occurred despite the length of aftercare (as long as 8 years).

Symptoms Of Chemical Dependence

The symptoms typically found in those personnel chemically dependent on narcotics are:

1. Unusual changes in behaviour, with frequent mood swings; periods of depression, anger, irritability, alternating with periods of euphoria
2. Withdrawal from family, friends, and colleagues
3. Obtaining ever increasing quantities of narcotics for their patients
4. Obtaining inappropriately high doses of narcotics
5. Sloppy and unreadable charting
6. Preference for working alone (to use anaesthetic techniques without narcotics, falsify records, and divert narcotics to personal use)
7. Refusal of lunch or coffee breaks
8. Frequently volunteering to relieve others
9. Volunteering for extra cases (especially cardiac cases where large amounts of narcotics can be used)
10. Volunteering for extra on-call
11. Frequenting the hospital when off duty (to stay near the drug supply)
12. Frequent requests for toilet relief (to use the drugs)
13. Disappearing between cases for long periods
14. Complaint of excessive pain by patients out of proportion to the amount of narcotic charted on the anaesthesia record
15. Wearing long sleeved gowns (to combat the subjective feeling of cold they experience when using narcotics)
16. Pinpoint pupils
17. Displaying evidence of withdrawal, diaphoresis and tremors
18. Weight loss and pale skin
19. Witnessed self administration
20. Coma or death

The primary trait of the disease is denial, the refusal to accept the reality of the chemical dependence. Those dependent on drugs are lonely isolated individuals unable to reach out for help. They feel guilt at their inability to stop using the drugs, shame at the prospect of being discovered, fear that, if detected, they will lose their medical licenses, career, and family. Most want to be detected because they cannot reach out for help. Family members are often aware of the addiction but they too feel guilt, shame, and isolation and therefore participate in a conspiracy of silence. They ignore obvious symptoms, make excuses to themselves and others for the addict's behaviour, and avoid taking action on suspicions. Many times the family members do not know to whom to go for advice and help. This is why education not only for the anaesthesia personnel but also for their family members is vitally important.

Management of Individuals with Chemical Dependence

Once a person is suspected of chemical dependence an intervention is planned. This is a structured meeting in which the addict is confronted with the evidence and consequences of the disease. The purpose is to initiate a program of recovery. Carefully planned in advance, the meeting is led by an experienced person, and may be attended by family members and colleagues. An intervention is not a punitive attack but a *supportive* act of caring. It should stress concern for the well being of the individual, his/her family and patients. At the time of the intervention a definitive plan for inpatient treatment of chemical dependence must be in place. At our hospital the addict is personally escorted to a psychiatrist specialising in chemical dependence for immediate evaluation. Failure to comply with this action results in immediate dismissal. It is the psychiatrist who determines whether or not the person is chemically dependent. Although denial is common during the intervention, most admit to addiction either on the way to the psychiatrist or at the psychiatrist's evaluation. If deemed dependent the person is immediately admitted to an in-patient facility for the treatment of chemical dependence so that no time is allowed for the addict be alone.

A one to two month period of inpatient treatment is followed by a variable length intensive treatment in an outpatient program (0-6 months). The purpose is the safe withdrawal of the addictive drugs, help in accepting chemical dependence as a chronic disease to be treated the rest of life, and the development of different attitudes and coping skills that will help maintain a drug free lifestyle (detoxification, education to overcome denial, and behaviour modification therapy). This is followed by years (if not a lifetime) of an aftercare program including group sessions, counselling, random drug screens, and the administration of alcohol or narcotic antagonists, if necessary.

Criteria For Return To Work

Whether or not an anaesthesiologist who has been addicted to narcotics should be allowed to return to the workplace is the subject of debate. While there is no documented evidence that anaesthesia personnel addicted to narcotics have harmed any patient, there is strong evidence that an addicted person is a safety hazard to himself (coma or death from overdose or suicide). The criteria for a successful return to work include:

1. Completion of a treatment program for both the addict and close family members
2. Acceptance of the disease of addiction and motivation to remain drug free, with acceptance of the need for continued treatment and monitoring
3. Support within the Department of Anaesthesia, the family, and colleagues for the continuing aftercare of the addict.

A continuing care contract is essential for successful recovery to continue. This contract may be with the treatment centre, the anaesthesia department, and/or the State Medical Society. The contract at our institution is very strict and the recovering addict agrees to:

1. Abstain from all mood altering drugs for life
2. Attend weekly self-help group meetings
3. Attend weekly group meetings for recovering physicians
4. Attend a weekly aftercare therapy session with a counsellor specialising in chemical dependence
5. Meet monthly with a primary care physician who is responsible for ongoing medical care
6. Meet monthly with a psychiatrist specialising in addition
7. Submit to random, witnessed urine drug screening
8. If narcotics were the addictive drugs, take naltrexone 3x/week before a witness (this provides extra physical insurance against relapse and reassurance to the department that an anaesthetist impaired by the use of narcotics will not be caring for patients)
9. If alcohol was the additive drugs, take disulfuram daily before a witness
10. Meet monthly with the Department Chairman (faculty) or Residency Program Director (residents)
11. Report monthly to a member of the State Society's Impaired Physicians Program Participants in the recovering addict's aftercare treatment program must give formal written evaluation to the State's Medical Society every three months.
12. Participate in family therapy
13. Within the workplace the recovering addict cannot be on call for three months or handle narcotics for three months following the return to work.

While these criteria are strict, they offer significant structure to the aftercare program and are necessary for a successful recovery. If the recovering addict does not comply with these criteria they are dismissed from the department. To date, all chemically dependent members of our department who have successfully completed an in-patient program and remain in a highly structured aftercare program have had no relapse over the six years since the start of our program.

Prevention is the key

Ways to prevent addiction include strict accountability of drugs and education. At our hospital, all narcotics and sedatives (benzodiazipines and ketamine) are locked in an automated drug dispensing unit (PYXIS®). Only a limited number of people have access to it. Access requires entry of a personal identification number and entry of a specific patient name. Each type of drug is kept in a separate drawer that opens only when that drug is requested. Visual count of the number of drug vials left in the drawer of the unit must be confirmed to the unit before the drawer is closed. If there is a discrepancy between the unit's count and the visual count, the person whose identification number was entered for the previous item is asked to explain the discrepancy. Unopened vials not used during the surgery are returned. Drugs drawn into syringes, but not used, are wasted with a witness present. The system limits easy access to drugs but certainly doesn't prevent drug abuse.

There must be education of medical students, residents, consultants and their family members concerning the prevalence as well as the signs and symptoms of the disease. Opportunities for reduction of stress should include discussion of job and emotional stresses and/or via exercise. Education has proven the most useful because family members and colleagues have known to whom they can go to discuss their concerns. The earlier that treatment is started following chemical dependence, the better the chances of lifelong recovery.

What is the Future of CME?

by Professor R M Jones, St Mary's Hospital Imperial College, London.

Medicine is a self-regulating profession. This is a privilege granted by the State through an act of parliament. The Medical Act of 1858 provided the basis for this self-regulation through the establishment of the General Medical Council. It is important to emphasize that professional independence is a privilege, not a right, and that the maintenance of independence cannot be assured without competent self-regulation[1].

In two articles published last year by Sir Donald Irvine, President of the GMC, the point is persuasively made that the performance of doctors needs constantly reviewing in a world that is rapidly changing[1,2]. This change encompasses both the recent enormous and ever increasing growth in medical knowledge as well as the increasing awareness and sophistication of the general public in health matters. I would commend both of these articles to all anaesthetists; the message they convey has profound implications for the way that all specialties, including Anaesthetics, self regulate their standards of practice and performance.

Participation in Continuing Medical Eeducation (CME) is an essential activity and is crucial to maintaining an appropriate knowledge base and in developing new skills. As a generalisation, the half-life of medical knowledge is of the order of 10 years. Thus, anaesthetists in their forties and fifties would needed to have renewed a very significant proportion of their knowledge base in order to be as well informed as a newly appointed consultant. The problem is with the sheer pace of change, not only in that aspect of medical knowledge needed to practice anaesthesia in the 1990's but also in the changing medico-legal environment in which we all practice and the impact on medicine of the information technology revolution.

The increasing importance of CME and CPD (Continuing Professional Development) is highlighted by the fact that during the UK's presidency of the European Union the CMO has chosen CME and CPD as the principal topics for a conference held during a meeting of EU Chief Medical Officers. This conference heralds an acceptance that there should be as much harmonisation of the CME requirements and activities of member states as possible. N.B. the terms CME and CPD are not synonymous; CPD implies activities that are not directly patient orientated, such as management, educational, budgetary and ethical issues. In addition, at the most recent meeting of DOCME (Directors of Continuing Medical Education) last October, this advisory body recommended to the Academy of Medical Royal Colleges that participation in CME and CPD should be mandatory not voluntary. This recommendation was made in the light of the growing pressure from patient groups, management, the GMC and defence organisations, that the profession be seen to be ensuring that all doctors are up to date and possess the core skills of their individual specialties. In effect DOCME recognised that unless the profession self-regulates this aspect of maintaining professional standards, the privilege of self-regulation will be lost.

Update - Information

EUROPEAN SPECIALIST MEDICAL QUALIFICATIONS AMENDMENT REGULATIONS 1997

On 31 December 1997, the above amendment came into force allowing greater flexibility in the transitional provisions which enable existing specialists to be entered onto the Specialist Register. In summary:

- The transitional period within which existing specialists may apply to the General Medical Council to have their names included on the Specialist Register is extended to **1 December 1998**.
- Greater flexibility has been introduced such that experience in a specialty and/or up to 12 months further training undertaken at the recommendation of the Authority, in addition to UK qualifications, are to be recognised by the STA in assessing a doctor for entry to the Specialist Register. Doctors who wish to be assessed for entry to the Specialist Register under these regulations need to apply to the STA, via the Royal College of Anaesthetists by **1 April 1998**.
- Doctors who need to undertake extra training (of up to 12 months) at the recommendation of the STA, can apply for entry to the Specialist Register before **1 December 1998**, but will be entitled to inclusion in the Specialist Register if they satisfactorily complete their further training by **1 December 2001**.

Further information on the arrangements for assessing doctors for entry to the Specialist Register under these Regulations will be issued shortly by the Specialist Training Authority.

Anaesthetists wishing to take advantage of these changes to transitional provisions are reminded of the deadlines and should address all correspondence to the College to **Mr Guy Wilkinson in the Professional Standards Directorate**.

EXAMINATIONS CALENDAR 1998/99

The Royal College of Anaesthetists Examinations Calendar for August 1998 to July 1999 has now been published and can be obtained from the Examinations Directorate at the College.

NEW PUBLICATIONS

Further to recent changes in the Regulations for the Primary and Final Examinations for the FRCA, an updated version of the Regulations may be obtained from the Examinations Directorate at the College (Direct Tel: 0171 813 1880). Sections that incorporate changes from the May 1997 version are listed inside the front cover for quick reference.

Update - Information

ANSWERS TO MOST FREQUENT QUERIES ABOUT THE EXAMINATIONS

As a quick reference, here are the answers to the questions we get asked most frequently about the FRCA examinations:

(1) Candidates need 12 months of approved training in the United Kingdom or Ireland before they can sit the Primary FRCA examination. No other overseas training is accepted.

(2) Candidates may not sit the Primary FRCA examination more than 4 times, and the Final FRCA examination not more than 6 times.

(3) Candidates need 30 months of anaesthetic training before they can sit the Final FRCA examination. Up to 12 months only of overseas anaesthetic training can be accepted; at least 18 months must be spent in approved posts in the UK or Ireland.

(4) The Primary and Final FFARCS(Ireland) examinations are considered entirely equivalent to the Primary and Final FRCA examinations respectively.

(5) Attempts at the FFARCS(Ireland) examinations are not currently included as attempts at the FRCA although this regulation will be reviewed in due course.

If you require any further information, please do not hesitate to contact the Examinations Directorate at the College.

It therefore appears likely that participation in CME will become compulsory in the future. Indeed, it is already for Fellows of the Royal College of Gynaecologists who will publish a white list in January 1999 of members who have completed the necessary CME requirements. There was a general feeling, aired at a recent workshop on CME organised by the Standing Committee on Postgraduate Medical Education (SCOPME), that not only was compulsion a likely event but that the pressure on Colleges to produce "white lists" was going to be difficult to resist.

Thus, it seems very likely that participation in CME is going to become a compulsory and potentially increasing part of all our lives. I fully appreciate that many people reading this article will find this observation an irritation (at the very least) and I must emphasize that this is not something being thought up and imposed by the Royal College of Anaesthetists. It is the result of increasing external pressures from a variety of sources which all Colleges and Faculties are having to face. In accepting the inevitability of compulsory CME, two issues emerge and need addressing. First, who is going to fund compulsory CME/CPD and second, what form should CME/CPD take. Both issues are difficult.

Even the relatively simple CME requirements and associated activities that have currently evolved are thought to cost in the region of £2000-£3000 per person per year. Currently the average amount available per trust appears to be in the region of £400 with the largest sum available said to be £1200 per year. If CME is compulsory who is going to pay for it? What form should CME take and how should it be recorded? There seems little doubt that passive participation in CME, such as attending lectures and conferences, appears not to have much impact on clinically relevant outcome measures3. However, active involvement in workshops, round table discussions and the like probably is more effective and CME should develop with a greater emphasis on the active involvement of participants. The problem is that this type of active-participation CME is much more labour intensive, time consuming and costly.

There has been much debate on how best to record CME activity. There is no doubt that the current points system has many drawbacks but the problem is quite what to replace it with. As in most aspects of CME the RCA cannot and would not wish to act alone on this issue. DOCME exists in order to harmonise the CME requirements of all Colleges and Faculties. As the format of CME and CPD evolves and develops so too will the systems for recording these activities. Another potentially contentious issue is to what extent, if at all, there should be an assessment whether participation in CME activities has increased an individual's knowledge base. This is an activity that could eventually result in a form of recertification.

There is also a growing awareness that every anaesthetist, of whatever status and affiliation, practising in circumstances where they may be autonomous (ie. unsupervised) must participate in CME and that they should keep up to date in the core knowledge and skills of our specialty. It seems very likely that each specialty will be asked to provide an outline of the core skills and knowledge required for safe independent practice. I have been working with the Chairmen of the Education Committees of the College (Pierre Foex) and the Association (Rajinder Mirakhur) to start to define these "core topics" and to initiate a discussion of their scope. I would very much welcome any suggestions concerning what topics and skills should make up this core (should, for example, each of us be skilled at using the fibre-optic laryngoscope?). Society has the right to expect that any independently practising anaesthetist should have up to date core knowledge and skills; this expectation would include non-consultant career grade staff as well as GP clinical assistants. It will be for the College and other competent providers to ensure that workshops and courses covering the agreed core topics are available on a regular rolling basis and accessible to all. In this respect discussions are ongoing concerning the organisation of regional CME activities and the use of teleconferencing is also being explored.

CME is just one aspect of professional standards and increasingly departments will need to be accountable for the quality and standards of care that they provide as a whole. Ultimately, this collective responsibility lies with the clinical director but each individual in the department bears a share of this collective responsibility in addition to the purely personal responsibility of keeping abreast of developments, practical as well as theoretical. However, the CME needs of individuals vary greatly but what an individual perceives as what is needed may not be what their peers would think. Self evaluation programmes are becoming available to assist an individual in identifying their educational needs. Used in conjunction with a review of quality of practice at the local level, and more goal orientated CME activities, self evaluation programmes should find a useful place in ensuring optimal use is made of the time available for continuing education.

I conclude by emphasizing the fact that the manner in which CME is evolving is something that is being driven by a variety of outside sources including the defence organisations, the GMC and patient interest groups. In a real sense society is demanding that not only do doctors keep up to date but that this is a recorded and verifiable phenomenon. Since becoming Director of Continuing Education and Professional Development I have received a number of letters complaining of the increasing regulations imposed on our professional lives and asking if participation in CME has ever been shown to do any good (there was yet another letter along these lines in the January Newsletter). Through the Professional Standards and Continuing Education and Professional Development (CEPD) Committees, the College has a duty to ensure that these external pressures are responded to in a thoughtful and appropriate manner. The net result may not be to the liking of every one reading this article (and probably even less palatable to those who are not) but doctors in all other specialties are undergoing broadly the same strictures. We go back to the fact that professional independence is a privilege not a right. If we do not maintain all aspects of our professional standards - and this includes CME - in a way that society wishes of us, someone else will do it for us.

Chairman, Continuing Education and Professional Development Committee.

Personal View 1:

JAMES ROCHFORD 1915-1979

by Dr J Bushman, Retired Fellow of the College.

James Rochford was a consultant anaesthetist at Barnet General Hospital when at the age of 64 he died following a cerebral haemorrhage. He trained at St Bartholomew's hospital between 1935 and 1940 and then served in the RAMC mostly in the Middle East. Here he became a Specialist in Anaesthetics and reached the rank of Major. Following his service in the Army he was a consultant anaesthetist at Barnet General and Clare Hall Hospitals. He was a man who taught by example and was a great stimulus to all his juniors. He claimed that he never had the time to read but when discussing some anaesthetic subject would give a reference which frequently included the page number in the relevant journal or textbook.

In 1954 he was one of the founder members of the North London Group of Anaesthetists and he played an active part in the group until his death. He wrote very little, a chapter on ventilators in Evans and Gray, and a paper entitled "An Electronic Time Cycled Ventilator". This was published in the BJA in 1958 with Dr Welch and Mr Winks. This was quite courageous as at that time many anaesthetists believed that "the educated hand" of the anaesthetist was superior to any form of mechanically assisted ventilation. Rochford's machine was to become the first of the Barnet ventilators. The machine was a simple time cycled minute volume divider and was very easy to use. It was not the prettiest of machine but was very robust and reliable. The machines were built by Watsons of Barnet, the microscope manufacturers, whose factory adjoined the hospital site.

This led to the development of the Barnet Mark III, an extremely versatile machine, which could be time, cycled, volume cycled or pressure cycled. At the time the first of the Barnet ventilators were produced a succession of registrars were fortunate enough to come under Rochford's tutelage. These included Hilary Howells, James Freeman, John Collis, John Bushman and Doreen Browne. Hilary Howells went on to develop the Howells ventilator, John Collis developed the Cape Minor ventilator and John Bushman, as a consultant to Philips, aided the development of the Philips AV1 and the Philips AV3 ventilators, both direct descendants of the original Barnet.

Once freed from the reservoir bag the "educated hands" at Barnet began investigating a number of other interests. These included the measurement of mean airway pressure, central venous pressure, the blood pressure. This later was a non-invasive method using the automated inflation and deflation of an oscillotonometer cuff.

A method of detecting abnormal complexes in the ECG using analogue computers was also perfected. It is doubtful if this would have occurred without Rochford's stimulation and encouragement.

Rochford always maintained excellent relationships with industry, particularly with the development engineers, and those from Watsons, BOC, Cape and Devices were frequently seen in the anaesthetic department. This was a valuable additional stimulus to the junior staff.

He was one of the first anaesthetists in the country to use bronchial lavage for the treatment of asthma and he developed a technique using a double lumen tube so that the patient had one lung ventilated while the other was washed out.

Early in the 1960's the planning and building of an ITU was begun and it was opened on January 1965. This was adjacent to the recovery area and situated close to the main theatres. The anaesthetic nurses, the recovery nurses and the ITU nurses were all part of the same team and as a result they were a very highly trained and motivated group.

The countryside around Barnet had been a centre for horse-trading and tetanus was not an uncommon sequel to penetrating injuries. Since Rochford's expertise in ventilation was well known it was natural that Barnet should be designated a centre of expertise for the treatment of tetanus. This resulted in junior staff gaining valuable experience in the long-term ventilation.

James Rochford did much to change anaesthesia from an art form to a science, particularly by adapting from technology in industry to the needs of anaesthesia. He is remembered by all who worked with him with great affection.

Personal View 2:

HOW COULD A COURSE TAKING PLACE IN A REMOTE CORNER OF UGANDA BE SO IMPORTANT?

by Dr R Hutchinson, Consultant Anaesthetist, Harare Central Hospital, Zimbabwe.

My reason for choosing this topic is that there has recently been increased recognition by many including the World Federation of Societies of Anaesthesiologists (WFSA) that most anaesthetics in Africa are given by Non-physicians. As a result if anaesthesia is to be made available and safe for "all the peoples of the world" targeting of this group educationally has high priority. As you know there is a strong anti Nurse Anaesthetist lobby particularly in the USA and Brazil. But the situation in these countries is quite different. In some countries of Africa there are virtually no Anaesthesiologists. Professor Vickers, President of the WFSA, spoke on "Physician and Non Physician Anaesthetists - Is There a Real Conflict" at the final Plenary Session of the All Africa Anaesthetic Congress in Harare in April 1997. He said that in a Third World setting Non-physicians are no threat whatsoever to Physicians. I am sure most people working in the Third World would agree. So I thought a report of a meeting in Uganda where Anaesthesia is moving forward along a quite different route to the West might be of interest to Fellows of the College.

The First National Anaesthesia and Monitoring Equipment Course took place in Kabale, Uganda, on 1-6 September 1997. It was organised by Professor Henry Bukwirwa of Makerere University, Kampala. Professor Bukwirwa is currently President of the East Africa Association of Anaesthetists and a Board Member of the Africa Regional Section of the WFSA. Faculty included two Anaesthesiologists from Uganda and three from other countries. In addition, there were six technicians from Uganda headed by the Assistant Commissioner of Health Services/Engineering.

This group was backed up by an Anaesthetic Officer involved in Equipment Maintenance from Tanzania and a Technical Training Officer from Penlon, UK who supply the EMO and OMV draw over vaporisers used in Uganda for Ether and Halothane respectively. Delegates were about 30 Anaesthetic Officers (Non-Physicians) from Uganda and one from Kigale, Rwanda. The course lasted a week and was repeated with a second group so that the input reached every hospital in the country. Working hours were 8.15 a.m. to 10.30 p.m. Why was this course so important?

This was certainly not the first course in the world devoted to equipment. One such was held in London by the Royal College of Anaesthetists in association with the Institute of Electrical Engineers in November 1996. The final session focused on Anaesthetic Simulators. The Kabale Course could not have been a greater contrast. It took place in a remote town in the mountains of

Western Uganda on the borders of Tanzania, Rwanda, and the former Zaire. The Dian Fossey Gorilla Park was only two hours drive away. Sometimes the electricity failed and once or twice water from the tap looked more like mud.

The purpose of the course was to empower users of Anaesthetic Equipment not only to understand their machines but also to maintain them and carry out simple repairs. It is well recognised that Anaesthetists should understand something of the workings of the equipment they use. It is equally well recognised that the establishment of efficient anaesthetic equipment maintenance and repair is essential. The importance of the Kabale course was that there were lectures on how the equipment works TOGETHER with opportunities for hands on stripping it down. Common faults and their causes were identified. The users were taught which of them they can rectify THEMSELVES and how to do this using very simple equipment. What was achieved as seen by an outsider?

Appropriate Technology

Anaesthetic Equipment provision in Third World African countries is developing along two distinct lines. In a number of countries anaesthetists strive to keep up with technological developments in the West. One can understand the attitude of "Nothing but the Best" for my Department/Hospital/Country. Unfortunately in practice the latest technology, if it ever gets into use, soon collapses because of the unavailability of money and skills for routine servicing and repairs. More importantly anaesthetists, often non-physicians, are trained on this "High Tec" equipment and then sent out to the periphery were it may not be available and even if it is there are no technicians to carry out the necessary maintenance. The other school of thought says that the most important facet of anaesthetic equipment is that it should be properly maintained and accurate. In addition it should be simple to use and understand so that user error is minimised. Both schools accept the need for the best possible training for the user. At Kabale, because the equipment used in Uganda is basically simple, very detailed knowledge and skills could be imparted to the users. Once you understand the obturator and slide mechanism of the OMV Halothane vaporiser it is quite easy to see how the pointer will stick if dirt gets on to the slide and more importantly how to rectify the problem with just a screw driver.

ANAESTHETISTS and TECHNICIANS were living and working together and learnt to appreciate the role of the other. Both groups could see what simple problems did not need to be referred. The opportunity was also used to up grade the peripheral hospital technicians. Appropriate ACTION to take when equipment failed was discussed by all and the mechanism of referral made clear.

All DELEGATES CONTRIBUTED. By sitting the course in the periphery delegates were on the spot all the time. They saw their leaders WORKING very hard and enjoyed doing so themselves. Everyone was encouraged to talk about his own problems and these were dealt with sympathetically. Delegates had to report and present their group work with different speakers presenting on each occasion.

Plans are already in place for FOLLOW UP to ensure that improvements in anaesthetic equipment maintenance do take place.

In the West, anaesthetists are pressed by the manufacturers to use ever more complex equipment and more expensive drugs. This is unrealistic in a Third World setting. In East Africa the problems of "High Tec" Anaesthesia have been fully appreciated. The decision has been taken to remain with simple equipment and to move forward by training its users in greater depth.

Footnote

Of great interest was the reaction to the course of the non physician Anaesthetic Officer from Kigale, Rwanda. He and one Belgian Doctor, currently away, are in charge of a programme set up by the Red Cross to train Anaesthetic Officers for Rwanda. Some of the trainees are nurses trained on the job by Aid Doctors and some are straight from school. They have a curriculum but have problems finding lecturers and have almost no books. The equipment consists of four High Tec Anaesthetic machines left behind by an Aid Agency and one EMO. There is of course no N2O. This man fully appreciates the value of simplicity in his situation and plans to try and establish training programmes based on simple equipment. Since returning from Uganda I have been asked to advise on equipment by a Physician trying to set up some sort of Anaesthetic Training in Eastern Angola. The advice was of course "Keep it Simple".

Correspondence

Sir,

THOSE MAGNIFICENT MEN AND THEIR FAILING MACHINES

From Dr J P Newell, Addenbrooke's Hospital, Cambridge.

Your Editorial in the January 1998 Newsletter neatly coincides with the FRCA "failing machine" taxiing outside the SHO departure lounge. Little wonder some trainees are as bemused as their trainers.

I agree it is time to question the purpose of the current examination. Squashing two exams into the first 36 months and leaving the rest of SpR training (soon to be 5 years?) to underdeveloped "assessments" is not the way forward. Can I highlight just two problems? The first is immediate. Trainees perceive the Final FRCA as a test of their commitment to the specialty (which it is). Rarely is it seen as the natural summation of theory and practice implied in the Syllabus. However, most SpRs (80%+) presented with modular training in the sub-specialties, and encouraged to integrate clinical practice and reading, will pass at the first attempt. That is our experience: the problem is in moving this process to the SHO years at short notice.

The second problem, as you point out, is the future. What knowledge and education will the anaesthetists need in, say, 10 years time and can or should we "examine" it with the traditional failing machine?

Adapting to change, generating new solutions and rejecting the old seem paramount. In other words, more emphasis on critical thinking and less on memory recall. I think that a dissertation, based on the trainee's declared clinical interests in the final SpR years, would be relevant.

Whatever the solution to the problem of assessment of training let us make sure that future examinations are clearly integrated with education and training; not so much a barrier, more a natural step forwards.

Sir,

CLINICAL AUDIT

From Dr A J G Gray, Norfolk and Norwich Healthcare NHS Trust

Anaesthetists are good at clinical audit (look at the number of anaesthetists who are Chairmen of their Trust audit Committees) so why does the College not do more to initiate and promote audit. For example, the annual clinical audit conference was held in London in November. Many Colleges had stands - surgeons, obstetricians, pathologists, ophthalmologists, physicians and others. There was no stand from the Royal College of Anaesthetists. Why not? Nobody available? No money? No ideas?

Secondly, the College only writes to audit leads; apparently it is too expensive to write to all Fellows individually about audit. Has the Editor of the Newsletter been asked for space for a regular bulletin on audit affairs that would reach all Fellows; it works for the pathologists. Or is there nothing to report?

I am sure there is a lot of good work going on in the Quality of Care Directorate. Can we not tell everybody, inside and outside the College, about it, and work to improve the quality of anaesthesia that we deliver.

A reply from Professor D J Hatch, Chairman, Professional Standards Committee: Dr Gray raises some interesting points about the communication of this College to it's Fellows with regard to audit and the work of the Professional Standards Committee.

I hope that he read with interest two items in the January letter about work originating from this committee: the Patient Liaison Group and the Critical Incident Study. I acknowledge that there is no regular input into the College newsletter, however this is a suggestion that we will take seriously. In the past we produced an issue of a audit newsletter that was distributed to all Fellows. Unfortunately, we had very little response or submissions from our Fellows, suggesting that we would have difficulty in producing further issues. Dr Gray's suggestion that the College has a regular section in this newsletter on clinical audit and the work of the committee therefore may have some merit.

With regard to the National Clinical Audit conference he refers to, we originally explored the possibility of having a joint stand with a number of other Colleges, as the costs for individual stands were outside our budget for this area of work. However, in the end this did not prove possible. We would hope to have a stand at the same conference next year when we will have more up to date material to demonstrate, including the anaesthetic audit recipe book that we will publish later year and the Critical Incident Study materials.

Despite a reduction in NHS(E) funding to the Colleges for audit, we will continue to ensure that audit leads within departments are kept informed about College activities in this area, in the hope that they will disseminate this information to their colleagues. The recent change of name of the Professional Standards Committee recognises the fact that although audit is important, it is only one of the ways in which the College is committed to the maintenance of standards.

Sir,

SIMULATOR TRAINING AND RESEARCH SHOULD BE COMPLEMENTARY AND COLLABORATIVE

From Drs F Forrest, M Tooley and S Mather,
Bristol Royal Infirmary.

Those of us involved in the running of the Bristol Medical Simulation Centre (BMSC), would like to comment on the recent articles on simulation that appeared in the November issue of the Newsletter.[1,2]

In his article David Wilkins accurately described the origins of BMSC and the funding of this project from the Special Trustees of the United Bristol Hospitals Trust. However, it is now ten months since the centre opened in January. A number of organisational issues have been addressed during this time. Most significant has been the reorganisation of the project which took place in June. The wholly commercial nature of the project did not sit well with the clinicians whose primary interest lay in teaching and training. From a practical standpoint these people are whole time employed and in a difficult position to deliver the commercial requirements. The NHS and University consultants now have "free" time to develop training and research programmes. We have moved forward and a number of us in Bristol have been working hard to try and make the project a success. We are now beginning to see reward for our efforts.

We have been most impressed by the work of the ACCESS team. We are certainly as committed to research and development of simulators for education as the Cambridge group. As such we hope good lines of communication will be established between the different simulator user groups whatever the simulator they are using. With another Human Patient Simulator in Scotland in the near future, and we hope a successful joint venture between Belfast and Dublin, we already have a network of interested parties.

Dr Byrne is correct that there is a paucity of research coming out of Europe at present. This may reflect the variety of simulators in use and the fact that much effort is required by these workers to develop the non-commercial systems and fund continued work with them. In the United States, some years ahead in high fidelity simulation and with two rival commercial groups, there is a considerable body of work looking not just at Crisis Resource Management for teaching but more fundamental aspects of education using a simulator. The wealth of information presented at the recent Meeting of the American Society of Anesthesiologists in San Diego reflected this.

Those of us working in this field are primarily interested and enthusiastic educators. Good and cordial communication should be the aim of this group as we try to move forward together whatever the system of simulation we are using. With the changes brought about by the introduction of the Specialist Registrar grade and the expected reduction in trainee numbers over the next few years we suspect most permanent clinicians will be distracted by questions of service delivery rather than progressive educational methods. Thus, we suspect that simulation will continue in centres with the expertise with room for many David's if only one or two Goliath's!

Sir,

MEDICAL WRITERS GROUP

From Dr H T Davenport, Retired Consultant Anaesthetist, Northwood, Middlesex.

The Medical Writers Group of the Society of Authors may be of interest to Fellows who have written or are writing a medical or dental book for publication.

When the Society of Authors was founded in 1884, Bernard Shaw stated: "We all, eminent and obscure alike, need the Authors' Society". The Medical Writers Group was formed in 1979 to promote their special interests and to defend their rights.

A small permanent staff, based in Chelsea, London, give individual advice (especially contract vetting), tackle legal action of general interest, publish a journal for authors, produce a variety of Quick Guides on different aspects of authorship, arrange writing seminars and social events, and provide access to many other facilities. There are groups in Scotland and Northern England. Annual awards for outstanding books are chosen by Society Committees - the Medical Writers Group adjudicating the Royal Society of Medicine Prizes.

There is rarely much financial gain from writing or editing medical textbooks, and amicable relations with publishers are essential for the endeavour to be rewarding. Details of the types of membership, subscription rates (tax deductible) and the services provided can be obtained from 84 Drayton Gardens, London SW10 9SB (Tel: 0171 373 6642 or Fax: 0171 373 5768).

I greatly wish I had been a member of this Group and had benefited from the Society's support when I first had to deal with publishers many years ago.

Sir,

RES IPSA LOQUITUR

From Dr W Ryder, Royal Victoria Infirmary, Newcastle.

May I be permitted to reply to the article by Dr Heneghan on Res Ipsa Loquitur which appeared in the January issue of the Newsletter?

I enjoyed the article which made a valuable contribution to the understanding of those of us anaesthetists at the sharp end who are not experts in the law and who have, hither to, put too simplistic an interpretation on the principle of res ipsa.

There are, however, two or three points I would like to debate: -

1. For a "meticulous anaesthetic record" to suffice to persuade a court that there had been no negligence, I find rather disturbing. Whilst I am all in favour of proper, relevant and readable record keeping, it undoubtedly distracts the attention of the anaesthetists from the monitors and, much more importantly, from direct patient observation and care. And surely, in a critical situation the last thing you should be doing is filling in the forms meticulously? At best in that situation, an attendant should be delegated to observe, and to list in sequence, what you do and what you give to relieve the situation. This list should then form an important part of your defence evidence in place of the gap on your "meticulous" anaesthetic record and would act as a retrospective "aide memoire".

   At this point I am reminded of my three month indoctrination course in 1959 for entry to the Royal Air Force Medical Service. We were told they "didn't give a damn if the patient died, so long as we filled in all the forms"!

2. The issue of "rare and unlikely" is not quite so simple as Dr Heneghan implied. Firstly, events regarded as rare - and therefore unlikely - may not, in fact, be rare, but only rarely reported and reaching the light of day. I think this is largely what clinical incident reporting is about - i.e. to determine how frequently such an incident occurs and whether or not we need to alter our practice so as to make it rare and unlikely. How often, for instance, have any of us presented to a morbidity meeting an event we personally thought was unusual or unlikely, only to find that colleague Joe Bloggs, our senior by twenty years, had encountered and countered a similar event five times before?

Secondly, does the fact that "no cause was found" always imply rare and unlikely, and therefore no negligence? I recall a dental anaesthetic death in Cumbria some years ago in which a dentist, acting as his own anaesthetist incidentally, injected halothane IV instead of methohextone. A rare and unlikely event, surely, but very negligent nevertheless. No "cause" was found at post-mortem. In the example quoted, he actually did the same thing to his next patient before it dawned on him that something might be amiss with the "brietal". Two "rare" events in quick succession, so who needs a dental anaesthetic population of "50 million plus"?

In the actual example used by Dr Heneghan of a fit boy "dropping dead", were studies done for high viral titres to exclude acute, symptomless viral myocarditis which would not show up at post-mortem, but which is not uncommon.

It raises again a question we all ask ourselves frequently. Should we anaesthetise a patient with a history of recent viral upper respiratory infection? I can quote again from dental anaesthesia to illustrate my point. A "fit" girl of eight died under anaesthetic in a dentist's chair in Blyth, Northumberland a few years ago. Her grandmother gave the anaesthetist a history of "flu" the week before. No "cause" was found at post-mortem.

On the principle of res ipsa, and on a balance of probabilities, how would a judge find in that case?

3. That brings me to my third and last point of debate. Dr Heneghan argues that, by recording more of what we already frequently monitor (e.g. inhaled vapour concentration), or by seeking and recording other non-risky "firm evidence", we will inevitably record to "a legal standard of proof". I am not entirely convinced by this argument and not quite sure what he is implying. Is he advocating, by "legal standards of proof", that medical negligence judgements henceforth be based on evidence which is beyond reasonable doubt, rather than on a balance of probabilities? That would indeed be disturbing. In human biology and medicine, where almost everything is measured in shades of grey, and in anaesthesia and intensive care in particular, where parameters and requirements change rapidly and from moment to moment, I would hate to see more rigid standards of evidence applied than obtain at present.

May I be permitted one final and cynical thrust? Dr Heneghan clearly rejoices in the statement that "Trial by Battle" was abolished in 1819 and that judges can now judge only on the basis of witness evidence. It seems to me that the British judicial system has little to do with quality or quantity of evidence and justice and everything to do with who is the more powerful adversary (advocate, Mr Heneghan). What is that but "Trial by Battle"?

Please keep the interesting articles coming Dr Heneghan - if you are not too busy seeking election to the College Council!

A reply from Dr C P H Heneghan: Dr Ryder makes the point that in a critical situation we should not be filling in forms: I agree, and did say that we should only be gathering more or better evidence when the risk to the patient is not increased. Otherwise, recording should be retrospective, even if it increased the risk to our reputations.

I do not wish to imply that "rare" is easy to define, but to point out that whilst we may accept that rare things occur regularly - if infrequently - a judge may not, and may need convincing.

"Legal Standard of Proof" does not mean beyond reasonable doubt: that is the criminal standard of proof (perhaps we should not resist its introduction, as it usually operates in favour of the Defendant). I merely mean that a record intended solely as an aide memoire may have insufficient detail to form a record which a judge would have no hesitation in accepting. Remember that a court's purpose is to test the evidence and it may find the evidence wanting if it is apparently full of gaps.

Finally, I make no apology for delighting in the abolition of Trial by Battle, though my surprise at the abolition being delayed until 1819 was what I meant to express. However, I would expect Dr Ryder's view, that British justice has little to do with evidence, to be altered by spending some time in the courts. He would not see an American media trial here, he would see decisions based on evidence. He should remember that if the evidence does not represent the facts, it is not the Judge's fault. As is said of democracy, so of the adversarial system: it may not be much good, but everything else is worse.

Sir,

INTENSIVE CARE TRAINING FOR ANAESTHETISTS

From Dr P Radford, on behalf of the Specialty Training Committee for Anaesthetics, South Thames (West)

The recommendations of the Intercollegiate Board are the culmination of years of work by those working in the field and at College level. It is with regret, therefore, that we do not see how they can work. We agree with the doubts expressed by Fletcher, Ridley and Burchett in the January Newsletter.

There are three serious gaps between what is recommended and what is possible (or even desirable).

Firstly, there will not be enough recognised training posts for the senior house officers form the acute specialties in the limited number of accredited units.

Secondly, training scheme organisers across the country know that it takes two years to deliver the modular training that the College training guide expects us to provide in the first specialist registrar year: there is no "spare" year to fit in 6 months of medicine and 6 months of intensive care.

Finally, few anaesthetists regard a specialist registrar programme of with only two years in anaesthesia as adequate for a CCST in anaesthetics.

Report of Meetings of Council

At a meeting of Council held on **Wednesday, 17 December 1997**, Professor P D Wall was presented with the Dudley Buxton Prize.

Professor P D Wall

A summary of his Citation given by Dr D M Justins: The Dudley Buxton Prize is awarded triennially for meritorious work in anaesthesia or in a science contributing to the progress of anaesthesia. The Prize commemorates Dudley Buxton (1855-1931) who was anaesthetist to University College Hospital in Gower Street. There are some intriguing links between Dr Dudley Buxton and Professor Patrick Wall who is to receive the Dudley Buxton Prize today. The first is Gower Street. Pat Wall was Professor of Anatomy at University College, London (UCL) also in Gower Street from 1967-1990. The route to UCL was by Middlesex Hospital Medical School with graduation in 1948. Between 1948-1959 Pat Wall worked at Yale, University of Chicago, Harvard and the Massachusetts Institute of Technology (MIT) in Boston. From 1959-1967 he was Professor of Physiology at MIT. In 1967 he returned to take up the post at UCL. In 1972 he added Visiting Professor at the Hebrew University, Jerusalem a post which he still holds. Since his retirement from UCL Pat Wall has continued active research as Professor Emeritus of Physiology on the St Thomas' Hospital campus of UMDS (United Medical and Dental School) and he has also found a home for his editorial activities here at the Royal College of Anaesthetists.

Pat Wall has made a massive contribution to the science which underlies anaesthesia. More than 300 papers spanning 50 years bear witness to this contribution.

Dudley Buxton stated that the anaesthetist must be scientifically as well as practically educated in his art. More than anyone else Pat Wall has been responsible for bridging the gap between the basic sciences and the clinical practice of pain management.

Dudley Buxton was one of the first to recognise the influence of psychological factors on patient well being. Likewise, Pat Wall has always recognised that pain is a multidimensional problem and he has collaborated with scientists and clinicians from many disciplines throughout his career.

Undoubtedly his most famous collaboration has been with a psychologist Ron Melzack, a psychologist-cum-physiologist and Pat Wall, a medically qualified scientist produced the pivotal paper of 20th century pain research. "Pain mechanisms: a new theory" published in Science in 1965. In 1962 they had published in Brain a more general theory on sensory mechanisms which had rather escaped notice but the Gate Theory was revolutionary.

The Gate was a theory but the ideas were subsequently given strong support by basic and clinical research, much of it involving Pat Wall. Although the Gate has evolved into a complex neuromodulatory system of facilitatory and inhibitory controls, our knowledge is still in the final analysis, based on that initial theory; and it was that theory which was the prime stimulus for the exciting explosion in pain research which has occurred in the last 30 years. Pain has moved out of the shadows of neglect and into the limelight where it has been recognised as a major clinical problem for virtually every branch of clinical medicine and also as a suitable subject for basic research. Pat Wall has argued persuasively that relief from pain is a basic humanitarian right.

With Sweet the neurosurgeon, Pat Wall was able to apply the concepts of the Gate Theory to produce a clinically useful treatment. Transcutaneous Electrical Stimulation (TENS) which is widely used today. In a more recent example of applying basic science to clinical problems Pat Wall in 1988 wrote an editorial in the Journal Pain which promoted the concept of pre-emptive analgesia and the subsequent debate has encouraged anaesthetists to look more closely at the way in which they manage acute pain.

Very importantly Pat Wall also advocated the multi-professional approach to pain management. The International Association for the Study of Pain (IASP) has done so much to promote this collaborative approach to pain research and management and Pat Wall was one of those enlightened individuals responsible for founding the organisation.

Dudley Buxton wrote a textbook "Anaesthetics: their uses and administration" which ran to six editions from 1888 to 1920. Pat Wall along with his friend Melzack, has edited the "Textbook of Pain" which is the standard major textbook for basic scientists and clinicians alike. The fourth edition is in preparation. As in Buxton's book there is an emphasis on the need to understand the basic science in order to begin to understand the clinical problems. Pat Wall was the founding editor of the Journal Pain in 1967 and still continues as Editor-in-Chief. Under his stewardship this Journal has assumed the pre-eminent place in pain literature by only accepting papers of the very highest scientific standard. Pain has published the work of many anaesthetists thereby recognising the major contribution that anaesthetists make to research into both the mechanisms and management of pain. Pat Wall is a member of the Research Committee of the Royal College of Anaesthetists.

Pat Wall has never been afraid of engaging in intellectual combat. His presence greatly enlivens any scientific meeting. He has championed unfashionable causes such as the medical use of cannabinoids and he has made a public defence of ethically conducted animal research. He is a member of the Scientific Committee of the RSPCA. He is a man who has achieved greatness yet he is approachable and genuinely interested in the ideas of others. In fact he thrives on discussion and is always bursting with ideas and infectious enthusiasm. His thinking is imaginative and leaps way beyond any narrow confines. He is capable of looking at something from a totally unexpected angle and has very wide-ranging interests.

Professor Patrick Wall has received honours from all around the world and he is a Fellow of the Royal Society. He has indeed done truly meritorious work in science contributing to the progress of anaesthesia and is richly deserving of the Dudley Buxton Prize.

The following were appointed/re-appointed **COLLEGE TUTORS**:

Oxford Region
Dr A Kapila, Royal Berkshire & Battle Hospitals, Reading
[in succession to Dr C Verghese]

North Thames (West)
Dr E Whitehead, Ealing Hospital
[in succession to Dr M M Meurer-Laban]

North Thames (Central)
Dr G Timmins, Colchester General Hospital
[in succession to Dr S I P Mackenzie]
Dr P Dodd, King George Hospital, Goodmayes
[in succession to Dr M Y Khan]

North West
Dr S Costigan, Furness General Hospital
[in succession to Dr V Govenden]

South West
Dr J Dunnet, Frenchay Hospital, Bristol
[in succession to Dr A Manara]

South Thames (East)
*Dr J B Broadfield, King's College Hospital

Wales
Dr P Baynham, Prince of Wales Hospital, Merthyr Tydfil
[in succession to Dr B Jenkins]

West Midlands
*Dr I P Hine, Hereford Hospitals NHS Trust
*Dr R D Patel, New Cross Hospital, Wolverhampton

The following were awarded **CERTIFICATES OF COMPLETION OF SPECIALIST TRAINING**:

Northern and Yorkshire
Dr Andrew John Berrill
Dr Paul Nicholas Charlton
Dr Hans Klein
Dr Susan Lesley Lindsay
Dr Nicola Jane Snook

Trent
Dr Brynley Roy Baxendale
Dr Michael Andrew Norris
Dr Paul Edington Shannon
Dr Howard Michael Thompson
Dr Guy Richard Quentin Veall
Dr John Edward Hendon Ward
Dr Ian James Wrench
Dr Richard Peter Wroth

North Thames (West)
Dr Stephen James Bates
Dr John Roy Fernandes
Dr Charles Robert Garcia-Rodriguez
Dr Ayad Abdul Karem Shakir
Dr Alison Elizabeth Shawe

North Thames (Central)
Dr Stephen Gerard Brosnan

North Thames (East)
Dr Stylianos Panayiotou
Dr Jeremy John Radcliffe

South Thames (East)
Dr Helen Maria Daly
Dr Susan Joanna Milroy
Dr Paul David Noble
Dr Babaseyi Oyedele Oyesola
Dr Jacqueline Sarah Porter

South Western
Dr Nicholas Julian Kennedy
Dr Andrew Keith McIndoe
Dr Emert White

West Midlands
Dr James Ernest Craggs
Dr Craig William Stenhouse

North Western
Dr Gerard Andrew Dempsey
Dr Robert Hamish Paton
Dr Mansoor Ahmad Sabar

Wales
Dr Amisha Mehta

Aberdeen
Dr Alan Donald Thomas

Edinburgh
Dr Joyce Cameron Stuart

Glasgow
Dr William John MacRae
Dr Jennifer Susan Walker

****Re-appointment.***

At a meeting of Council held on **Wednesday, 21 January 1998**, the following were appointed/re-appointed **COLLEGE TUTORS:**

North Thames (East)
Dr S Harrod, St Bartholomew's Hospital
[in succession to Dr H Hackett]
Dr J Durcan, Broomfield Hospital, Chelmsford
[in succession to Dr N Huddy]
Dr F Ogunyemi, Newham Hospital

Provisional Educational Programme 1998/99

MEETINGS

GOLDEN JUBILEE MEETING

18/19 MARCH 1998

A two day Golden Jubilee meeting on **"Progress in Anaesthesia"** to be held at the Royal College of Surgeons of England. The Joseph Clover Lecture and AGM will be held on the afternoon of 18 March and the Golden Jubilee Dinner will be held in the evening at The Guildhall in the City of London.

TRAINING PARAMEDIC TRAINERS

18 MAY 1998

[Please note the change of date]

A comprehensive one day Seminar to be held in the Lecture Theatre at the College.

CONTINUING MEDICAL EDUCATION DAY

10 OCTOBER 1998

A one day meeting organised jointly by the Association of Anaesthetists of Great Britain and Ireland and the Royal College of Anaesthetists to be held in London. The meeting will consist of 18 lectures held in 3 different lecture theatres, enabling participants to attend a total of 6 presentations in the course of the day.

SYMPOSIUM

5-6 NOVEMBER 1998

A two day meeting on **"Pharmacology in Anaesthesia - 50 Years on"** to be held at the Institute of Engineers in London.

ANNIVERSARY FORUM

17 MARCH 1999

A one day meeting on **"Endocrine Problems and Anaesthesia"** to be held at the Royal College of Surgeons of England. The Frederic Hewitt Lecture and AGM will be held in the afternoon and the Annual Dinner will be held in the evening *(venue to be confirmed)*.

SCIENTIFIC MEETING

7 MAY 1999

A one day meeting on **"The Respiratory System in Anaesthesia and Intensive Care - The Lung, Airway Diaphragm and Trauma"** to be held at the Institute of Engineers in London.

TRAINING PARAMEDIC TRAINERS

24 MAY 1999

A comprehensive one day Seminar to be held in the Lecture Theatre at the College.

COURSES

BASIC SCIENCES FOR ANAESTHETISTS COURSE

19-30 JANUARY 1998

This course is intended for those studying for the Primary Examination and consists of two weeks of full time lectures on anaesthetics and those aspects of physiology, pharmacology and statistics that are of interest to anaesthetists. Lectures will take place from 09.30 to 17.30 Monday to Friday.

FINAL COURSE

16 FEBRUARY-6 MARCH 1998

This course is intended for those studying for the Final Examination and consists of three weeks of full time lectures on anaesthesia.

COURSE ON CURRENT TOPICS IN ANAESTHESIA

8-12 JUNE 1998

This course consists of lectures, each of which is followed by ample time for discussion. It is intended for Consultants and Senior Anaesthetists who feel they may benefit from a refresher course in the latest techniques.

BASIC SCIENCES FOR ANAESTHETISTS COURSE

6-17 JULY 1998

This course is intended for those studying for the Primary Examination and consists of two weeks of full time lectures on anaesthetics and those aspects of physiology, pharmacology and statistics that are of interest to anaesthetists. Lectures will take place from 09.30 to 17.30 Monday to Friday.

FINAL COURSE
21 SEPTEMBER-9 OCTOBER 1998

This course is intended for those studying for the Final Examination and consists of three weeks of full time lectures on anaesthesia.

COURSE ON CURRENT TOPICS IN ANAESTHESIA
9-13 NOVEMBER 1998

This course consists of lectures, each of which is followed by ample time for discussion. It is intended for Consultants and Senior Anaesthetists who feel they may benefit from a refresher course in the latest techniques.

BASIC SCIENCES FOR ANAESTHETISTS COURSE
25 JANUARY-5 FEBRUARY 1999

This course is intended for those studying for the Primary Examination and consists of two weeks of full time lectures on anaesthetics and those aspects of physiology, pharmacology and statistics that are of interest to anaesthetists. Lectures will take place from 09.30 to 17.30 Monday to Friday.

FINAL COURSE
15 FEBRUARY-5 MARCH 1999

This course is intended for those studying for the Final Examination and consists of three weeks of full time lectures on anaesthesia.

COURSE ON CURRENT TOPICS IN ANAESTHESIA
7-11 JUNE 1999

This course consists of lectures, each of which is followed by ample time for discussion. It is intended for Consultants and Senior Anaesthetists who feel they may benefit from a refresher course in the latest techniques.

Meetings are open to all anaesthetists and other interested medical practitioners. Application forms will be sent before all MEETINGS to Fellows and Members (paying the annual subscription) of The Royal College of Anaesthetists.

Application forms for COURSES may be obtained by writing to the Education Department at the Royal College of Anaesthetists, 48/49 Russell Square, London WC1B 4JY (Direct Tel: 0171 813 1888 or e-mail: educ@rcoa.ac.uk).

Payment for all courses and meetings can now be made by credit card.

Outside Meetings

Association of Anaesthetists of Great Britain and Ireland

15 January 1998 Consultants Update Day (Queen Elizabeth II Centre, London). Morning Session: Association of Paediatric Anaesthetists. Afternoon Session: Plastic Surgery and Burns Anaesthetists.

16-17 January 1998 Winter Scientific Meeting (Queen Elizabeth II Centre, London). Specialist Session: European Society of Regional Anaesthesia (Great Britain and Ireland Section).

15-17 April 1998 Group of Anaesthetists in Training Annual Scientific Meeting and Linkman Conference (Nottingham).

Further information can be obtained from: Mrs Louise Watts, Ohmeda Educational Co-ordinator, Association of Anaesthetists of Great Britain and Ireland, 9 Bedford Square, London WC1B 3RA (Tel: 0171 631 1650).

Appointment of Fellows to Consultant and Similar Posts

REAH Dr G
Calderdale Healthcare Trust, Halifax.

Deaths

The College was saddened to note the deaths of the following Fellows:

BOLLEN Dr A R
Sale, Cheshire.

D'SOUZA Dr C A
Upton, Wirral.

HOLLOWAY Dr M H W
Minchinhampton, Gloucester.

KANE Dr G M
Eggington, Bedfordshire.

LOPES-SOARES Dr E
Lisboa, Portugal.

Dr R P Harbord MD FRCA

Dr Harbord, now of New Knoxville, Ohio, USA, has presented to the College a painting of the Ether Dome in Boston. The painting, by Dr Harbord, was made from a photograph of the Ether Dome taken in 1962. Dr Harbord was the first part-time Demonstrator in the University of Liverpool and after serving in mobile units in the RAMC during the Second World War he became the first full-time Reader and Head of Department of Anaesthesia in the University of Leeds before moving to the USA.

Order Form

LEAD CRYSTAL GLASSWARE

NIGHT CAP SET

I would like to order .... set(s) of the Night Cap Decanter and two glasses at a cost of **£34.10 (incl. VAT) plus £3.50 p&cp.**

I enclose £ .... ***[Please make cheques payable to "The Royal College of Anaesthetists"]***

DINNER DECANTER SET

I would like to order .... set(s) of the Dinner Decanter and two glasses at a cost of **£75.35 (incl. VAT) plus £3.50 p&cp.**

I enclose £ .... ***[Please make cheques payable to "The Royal College of Anaesthetists"]***

Mrs Eva Lazari
Royal College of Anaesthetists
48/49 Russell Square
LONDON WC1B 4JY

TO CELEBRATE THE COLLEGE'S GOLDEN JUBILEE

Lead crystal glassware handcut and engraved with the Royal College of Anaesthetists crest 1948–1998

The Decanter and glasses come in two sizes:

NIGHT CAP SET
Decanter: 14cm high
Two whiskey glasses: 6cm high **Price: £34.10 (incl. VAT) plus £3.50 p&p**

DINNER DECANTER SET
Decanter: 20cm high
Two whiskey glasses: 8cm high **Price: £75.35 (incl. VAT) plus £3.50 p&p**

Please send the order form (see opposite page) together with your cheque made payable to the **"Royal College of Anaesthetists"** to Mrs Eva Lazari at the Royal College of Anaesthetists, 48/49 Russell Square, London WC1B 4JY.
Please note that your order may be despatched direct from Burns Crystal Glass Ltd.

STATEMENTS

The purpose of this directive is not to limit the number of presentations, but to avoid duplicate presentation to major meetings of anaesthesiologists

This work will not

—*be presented* to a large English-speaking meeting of anaesthesiologists prior to the 1994 ESA meeting;
—*appear* in another form at that meeting;
—*be published* prior to the 1994 meeting in whole or abstract form in an indexed journal.

A. *Human studies* (to be signed by Senior Author if human subjects were used). I have satisfied the requirements of my institution or organization regarding the use of human subjects in research.

B. In consideration of the **European Society of Anaesthesiologists** taking action in reviewing and editing my/our submission, the author(s) undersigned hereby transfer(s), assign(s), and otherwise convey(s) all copyright to ownership in said work to the European Society of Anaesthesiologists in the event said work is published by the Society. I/We understand that this copyright assignment applies only to the abstract submitted herewith and does not apply to, or prevent, subsequent publication elsewhere of a full manuscript relating to the subject matter of such abstract.

GUIDE FOR AUTHORS
(English abstracts only)

ESA would like to encourage in every way possible the submission of abstracts from non-English speaking doctors. With this in mind, we ask that you please try to ensure that the abstract you submit uses the clearest English. We will try and help by correcting the English where necessary, but *you* must help us by sending papers that have been corrected as much as possible at source. We look forward to receiving your abstract papers for the ESA Congress in 1994.

Accepted abstracts will be published as a supplement to the February 1994 issue of *BJA—International Journal of Anaesthesia.* All abstracts which follow the guidelines presented below will be read by three blinded reviewers. Reproduction of accepted abstracts will be made by photoreduction to 80% of the original size. Abstracts cannot be retyped and thus will appear as they are submitted. It is therefore extremely important that you comply with the following simple rules.

1. The size and layout of abstracts are shown below. Line-spacing, subtitles, fonts (Times, Roman or similar) and font size (11–12/inch) should follow the style of the abstracts in this Supplement. Dot matrix printing is not allowed. If you have printing problems, submit your abstract on a 3.5 inch diskette using Words or Words for Windows version 2.0.
2. One figure or one table included within the borders of the abstract is allowed.
3. A maximum of three references may be included and should be listed at the end of the abstract in numerical order, and in accordance with the layout presented in the abstract example. They should be referred to in the text by corresponding numbers.
4. Relevant key words should be supplied on a separate page containing the title of the abstract and the list of authors to be used for the annual *BJA* index. Only the original of this page is needed.
5. Use the SI system for all data.
6. Submit one original, three unblinded and three blinded copies of your abstract. References which could unblind the abstract should also be removed.
7. Abstracts from non-English speaking countries should be checked as far as possible for linguistic errors before submission.
8. Only abstracts post stamped, or sent by courier, no later than October 1, 1993 will be considered for review.

The following absolute restrictions apply:

1. Abstracts submitted by fax are not accepted.
2. Abstracts which are not readable in English, will regrettably be returned without review.
3. Abstracts which are not complete, or abstracts that do not comply with the layout rules, will regrettably be returned.

Submit abstracts to:

Dr Sebastian Reiz, Department of Anaesthesia & Intensive Care, University of Umea, S-901 85 Umea, Sweden (Fax +46 90 131388).

Authors of rejected abstracts will be notified by mail (or by fax, if a fax number is supplied on the cover letter) approximately six weeks after receipt of the abstract. Authors of accepted abstracts will be notified approximately one month later.

12–16 May, 1993

PROGRAMME

10.40–12.10 Friday 14 May, 1993—Léopold II B
EPIDEMIOLOGY IN ANAESTHESIA AND INTENSIVE CARE (POSTER SESSION)

ABSTR. NO.

A new clinical score to predict difficult intubation A.1
J. Arné, P. Descoins, D. Bresard, J. Ariès and J. Fusciardi

An audit of the incidence and costs associated with post operative nausea and vomiting (PONV) following major gynaecological surgery in an inpatient population A.2
R. W. Morris, E. Ernst, D. J. Greaves, D. J. Layfield and R. F. Michael

Anesthesia for patients ≥ 90 years of age in emergency hip surgery A.3
S. Eleftheriadis, H. Kuppe, K. F. Klotz and P. Schmucker

A survey of sleep problems in surgical patients A.4
L. Beydon, A. Rauss, F. Lofaso, A. Harf and F. Bonnet

Indications for coronary revascularisation in vascular surgical patients A.5
M. Gosgnach, P. Coriat, M.-H. Fleron, M. Bertrand and P. Viars

Does routine preoperative coronary angiography modify outcome after aortic surgery? A.6
M. Gosgnach, M. Bertrand, A. Pironkov, P. Coriat and P. Viars

Outcome for patients in intensive care unit with acute renal failure requiring dialysis A.7
E. Ejlersen, M. B. Jensen and K. Eliasen

A national database for intensive care medicine in Sweden A.8
M. Karling

10.40–12.10 Thursday 13 May, 1993—Astrid
OUTPATIENT ANAESTHESIA (ORAL SESSION)

A comparison of midazolam and midazolam plus fentanyl for colonoscopy A.9
H. Dupont, J.-B. Nyarwaya and K. Samii

Evaluation of saccadic eye movements as an objective test during recovery from anaesthesia A.10
O. Paut, J.-L. Vercher, O. Blin, D. Mestre and J. Camboulives

Alizapride does reduce pain on injection of propofol: Comparison with lidocaine A.11
G. Zaouk, E. Gilbart, A. Dubois, D. Jacobs and E. Balatoni

Ondansetron 4 mg vs droperidol 1.25 mg in the prophylaxis of postoperative nausea and vomiting after alfentanil-supplemented inhalation anaesthesia A.12
E. Alon, P. M. Lenzlinger and T. Pasch

Double-blind comparison of ondansetron, droperidol and saline for prevention of nausea & vomiting after orthopaedic surgery A.13
T. J. Gan, R. Collis and M. Hetreed

Comparison of ondansetron, metoclopramide and droperiodol for the prophylaxis of emetic symptoms after gynecological laparoscopic procedures A.14
C. Geiger, O. Kick, H. Böhrer, J. Motsch and E. Martin

8.40–10.10 Friday 14 May, 1993—Dynastie A
PATIENT SAFETY, EQUIPMENT, MONITORING AND COMPUTERS (ORAL SESSION)

Clinical evaluation of the calibration of noninvasive continuous blood pressure measurement devices by means of oscillometric blood pressure measurements A.15
J. R. de Jong, H. H. Ros and J. J. de Lange

Technical aspects of jugular bulb oximetry A.16
C. De Deyne, J. Poelaert, J. Decruyenaere and F. Colardyn

Is correlation of arterial and end-tidal carbon dioxide pressure during inhalation anaesthesia better with laryngeal mask as compared to face mask? A.17
D. Ivens and C. Verborgh

Cardiac output (CO) measurement: Comparison of esophageal Doppler (ED) vs thermodilution (TD) A.18
J. Y. Lefrant, J. E. de La Coussaye, G. Aya, G. Saïssi and J. J. Eledjam

Cardiac output determined from pulmonary gas exchange A.19
B. Österlund, G. Johansson and S. Reiz

Preservation of humidity and heat of respiratory gases in patients with minute ventilation > 10 l/min A.20
C. Martin, L. Papazian, G. Perrin, P. Saux and F. Gouin

CLINICAL CIRCULATION

13.40–15.10 Wednesday 12 May, 1993—Astrid
Transesophageal echocardiography, myocardial ischaemia detection (Oral session)

ABSTR. NO.

Tolerance of preoperative transesophageal echocardiography in patients scheduled for aortic surgery........ A.21
M. Gosgnach, F. Le Bret, N. Smail, M. Beaussier and P. Viars

Dipyridamole-TEE and 24 h Holter-ECG as preoperative screening tests for coronary artery disease in patients with abdominal aortic aneurysm........ A.22
M. Östman, M. Karling, K. Karp, D. Teien and S. Reiz

Evaluation of haemodynamic indices of myocardial ischaemia in patients with coronary artery disease (CAD)........ A.23
P. Hohner, G. Johansson, S. Häggmark, V. Mehta and S. Reiz

The use of the cusum plot for determination of myocardial ischaemia threshold during atrial pacing in patients with coronary artery disease........ A.24
S. Reiz, G. Johansson, P. Hohner and S. Häggmark

Evaluation in intensive care of the fraction area change obtained by automatic border detection........ A.25
N. Liu, P. Catoire, J. Rosso, M. Saada and F. Bonnet

Sensitivity and specificity of mechanical and electrocardiographic myocardial ischaemia (MI) monitoring techniques........ A.26
P. Hohner, V. Mehta, M. Saada, S. Häggmark, E. Jansson, G. Johansson and S. Reiz

15.40–17.10 Wednesday 12 May, 1993—Astrid
Anaesthesia and intensive care related to cardiac surgery (Oral session)

Pulmonary and systemic vascular effects of isoproterenol, nitroglycerin and prostaglandin E1 early after cardiac operations in patients with pulmonary hypertension........ A.27
J. Alvarez, M. L. Camara, J. Cortinas, J. Cortes and A. Aris

Echocardiographic study of the induction with a low-dose of sufentanil for coronary artery surgery........ A.28
N. Bromberg, C. Decoene, E. Chammas, A. Pol and R. Krivosic-Horber

Gastric mucosal perfusion is better preserved during cardiac surgery when isoflurane rather than enflurane or propofol is used to maintain anaesthesia........ A.29
M. Mythen, D. Browne, C. Hamilton-Davies and A. Webb

Propofol/fentanyl-anesthesia in patients with highly depressed cardiac function........ A.30
H. Rauch, F. Fleischer, R. Haußmann, B. Böttiger and E. Martin

Accuracy of processed auditory evoked response in predicting movement during cardiac surgery........ A.31
H. Kuppe, K.-F. Klotz, S. Eleftheriadis, H. Gehring and W. Gerling

13.40–15.10 Thursday 13 May, 1993—Astrid
Clinical circulation—General I (Oral session)

Cerebral blood flow velocities (CBFV) during anaesthesia for gynaecological laparoscopic surgery........ A.32
J. C. Granry, C. Monrigal, J. P. Jacob and J. P. Monrigal

Neuroendocrine changes during pneumoperitoneum for laparoscopic cholecystectomy........ A.33
J. Joris and M. Lamy

Influence of pneumoperitoneum and posture on hemodynamic and stress response during anaesthesia for laparoscopic surgery A.34
S. Odeberg, O. Ljungqvist, P. Gannedahl, T. Svenberg and A. Sollevi

Effects of plasma volume substitution on right ventricle volumes and function using Elohes® and Plasmion®........ A.35
J. Y. Lepage, F. Garrec, J. M. Malinovsky, A. Cozian and M. Pinaud

Alternating right to left ventricular ejection: the case of occult cardiac tamponade........ A.36
C. Skourtis, L. Karalazos and D. Setzis

Determinants of systolic pressure variation in patients ventilated after vascular surgery........ A.37
M. Beaussier, P. Coriat, M. Gosgnach, M. Portilla, P. Kalfon and P. Viars

15.40–17.10 Thursday 13 May, 1993—Astrid
Clinical circulation—General II (Oral session)

The systolic pressure variation predicts response to volume loading in patients ventilated after aortic surgery........ A.38
P. Coriat, C. Gomez, G. Daas, A. Perel and P. Viars

Influence of chronic angiotensin converting enzyme inhibition on systolic pressure variation during anesthetic induction........ A.39
L. Puybasset, B. Oris, P. Coriat, M. Gosgnach and P. Viars

Ketamine does not prevent hypotension caused by induction of anaesthesia with propofol in elderly patients........ A.40
D. Blockmans J. Van Hemelrijck and H. Van Aken

Effects of nitrous oxide (N_2O) on systemic haemodynamics, regional left ventricular (LV) function and incidence of myocardial ischaemia (MI) in vascular surgical patients with coronary artery disease (CAD)........ A.41
P. Hohner, C. Backman, G. Diamond, A. Friedman, S. Häggmark, G. Johansson, K. Karp and S. Reiz

Epidural clonidine and myocardial ischaemia after abdominal aortic surgery........ A.42
J. P. Fulgencio, J. M. Rimaniol, M. Saada, P. Catoire and F. Bonnet

Influence of positive pressure ventilation on myocardial ischaemia after abdominal aortic aneurysm repair........ A.43
D. McCoy, M. O'Connor, A. Cunningham and R. Dwyer

15.40–17.10 Friday 14 May, 1993—Lèopold II A
EXPERIMENTAL CIRCULATION (POSTER SESSION)

ABSTR. NO.

Functional recovery after 24 h preservation of rabbit hearts in University Wisconsin Solution.............................. A.44
J. L. Fellahi, F. Ouardali, S. Mouren, J.-F. Baron, M. Diaby and P. Viars

Effects of hypertonic saline on coronary blood flow and myocardial performance of a blood-perfused isolated rabbit heart... A.45
S. Delayance, G. Mion, S. Mouren, J.-F. Baron, M. Diaby and P. Viars

Pre- and intraoperative prevention by β-blockers, propranolol and esmolol, of ischaemia-induced ventricular fibrillation..... A.46
M. Freysz, Q. Timour, L. Bertrix, J. Loufoua and G. Faucon

Endocardial endothelium modulates in vivo left ventricular performance A.47
S. De Hert, T. C. Gillebert and D. L. Brutsaert

Does captopril modify the arterial response to vasopressor substances?.. A.48
E. Le Pelley, T. Chataigneau, J.-P. Richer, R. Tricoche and J. Fusciardi

Does exogenous dopamine reverse cardiovascular depression induced by isoflurane during thoracic epidural blockade?...... A.49
C. Raner, B. Biber, J. Lundberg, J. Martner and O. Winsö

Local versus neurogenic vasodilator effects of desflurane and isoflurane in the small intestine A.50
H. Sundeman, B. Biber, O. Winsö, J. Martner and C. Raner

A comparison between various hemodynamic parameters reflecting preload during graded hemorrhaege in ventilated dogs... A.51
S. Preisman, A. Shneider, U. Pfeiffer and A. Perel

Influence of cervicothoracic epidural anaesthesia (C-TEA) on left ventricular (LV) contractility – an experimental study in pigs with autonomous blockade A.52
S. Reiz, E. Nyström, M. Tugrul, S. Häggmark and G. Johansson

8.40–10.10 Wednesday 12 May, 1993—Dynastie A
RESPIRATION (ORAL SESSION)

Recruitment of atelectasis during general anaesthesia: a CT-study.. A.53
H. U. Rothen, B. Sporre, G. Engberg, G. Wegenius and G. Hedenstierna

The respiratory compliance in normal and obese subjects during anaesthesia A.54
D. Mulazzi, E. Calappi and M. Croci

Continuous spirometry: an aid in the intraoperative respiratory monitoring – case reports.................................. A.55
G. Bardoczky, E. Engelman and A. d'Hollander

Influence of posture on the respiratory mechanics during anesthesia.. A.56
E. Engelman, G. Bardoczky and A. d'Hollander

Continuous monitoring of the ventilatory mechanics during anaesthesia & intensive care.................................. A.57
C. Py, J. P. Perdrix, P. Baçonnier, A. Eberhard, J. M. Fargnoli, F. Coppo and V. Banssillon

Continuous monitoring of SpO2 during total intravenous anaesthesia with ketamine and spontaneous ventilation............ A.58
L.-M. Joly and D. Benhamou

15.40–17.10 Thursday 13 May, 1993—Lèopold II A
RESPIRATION (POSTER SESSION)

Hypoxic events after general anaesthesia in the recovery room.. A.59
D. Degasperi, M. Vinelli, C. Festa and M. T. Fiandri

Influence of anaesthesia on postoperative hypoxaemia.. A.60
L. Georgiou, A. Vourlioti, F. Kremastinou, P. Stefanou and A. Tsiotou

Early postperfusion assessment of gas exchange and postoperative extubation outcome following coronary artery surgery.... A.61
P. Knapik, J. B. Richardson and I. McLellan

Cerebral perfusion during obstructive sleep apnea (OSA) A.62
E. Bålfors and K. Franklin

Respiratory effects of laparoscopic cholecystectomy (preliminary data).. A.63
M. A. Crea, L. Sollazzi, V. Perilli, E. Marana and R. Ranieri

Abdominal wall retraction may decrease anaesthesiological risks of laparoscopic cholecystectomy......................... A.64
Z. Vereczkey, B. Babik, J. Fogas, J. Méray and B. Baltás

Diaphragmatic function after bupivacaine cervical extradural analgesia for chronic pain therapy......................... A.65
E. Nyström, E. Jansson, B.-I. Wenngren, R. Sharma, F. Clerque and S. Reiz

Direct, indirect or flexible laryngoscopy after thryoidectomy?... A.66
L. Lacoste, J. Karayan, M. S. Lehuedé, P. Ingrand and J. Fusciardi

Day 0 or day 3 laryngoscopy after thyroidectomy?.. A.67
L. Lacoste, J. Karayan, D. Thomas, T. Vallet and J. Fusciardi

Laryngeal function as assessed by tussometry following topical anaesthesia A.68
R. P. Mahajan, G. E. Murty, P. Singh and A. R. Aitkenhead

METABOLISM, NUTRITION, ENDOCRINOLOGY

8.40–10.10 Friday 14 May, 1993—Lèopold II A
Thermoregulation (Oral session)

ABSTR. NO.

Core-peripheral temperature difference in early vs later extubation after coronary artery surgery A.69
P. Knapik, J. B. Richardson and I. McLellan

Effectiveness of core warming on net transfer of body heat across the skin A.70
P. Kulkarni and F. Carli

Effect of premedication with nifedipine on intraoperative hypothermia A.71
N. Vassilieff, N. Rosencher, D. I. Sessler, C. Conseiller and A. Lienhart

Preoperative skin-surface warming reduces intraoperative hypothermia A.72
Y. Camus, E. Delva and A. Lienhart

An investigation into the effect of passive and active cutaneous warming devices on intraoperative body temperature in elderly patients A.73
J. Bennet, V. Ramachandra and F. Carli

Fentanyl, as pethidine, inhibits post anaesthesia shivering A.74
P. Alfonsi, J.-M. Hongnat, C. Lebrault and M. Chauvin

8.40–10.10 Friday 14 May, 1993—Astrid
Anaesthesia and transplantation I (Oral session)

Modification of the renin-aldosterone axis during orthotopic liver transplantation A.75
J. de los Ríos, M. J. Iribarren, P. Monedero, F. García-Pedrajas and J. L. Arroyo

Measurement of sigmoid intramural pH during orthotopic liver transplantation A.76
Y. Auroy, M.-C. Gillon, H. Bismuth and C. Ecoffey

Changes in blood lactate, total body oxygen delivery and consumption during liver transplantation A.77
J. Carrera, P. Monedero, M. J. Iribarren, J. de los Ríos and A. Panadero

Oxygen consumption is dependent upon oxygen delivery in cirrhotics undergoing liver transplantation A.78
P. Piccinni, A. Tripepi, L. Rossaro, F. De Zen and A. Pierri

Effects of desmopressin (DDAVP) supplementation in brain dead organ donors (BDOD) on early recipient renal function .. A.79
R. Guesde, S. Ourahma, B. Riou and P. Viars

Fiberoptic bronchoscopy in brain dead organ donors A.80
B. Riou, R. Guesde, Y. Jacquens, R. Duranteau and P. Viars

10.40–12.10 Friday 14 May, 1993—Astrid
Anaesthesia and transplantation II (Oral session)

Total intravenous anaesthesia (TIVA) with propofol and alfentanil for renal transplantation A.81
M. Kirvelä, A. Yli-Hankala and L. Lindgren

Prevention of acute tubular necrosis by volume loading in kidney transplantation A.82
C. Mouquet, J. Luciani, M.-O. Bitker and P. Viars

Volume loading and hormonal factors in the prevention of acute tubular necrosis in kidney transplantation A.83
C. Mouquet, A. Carayon, F. Clergue, J. Luciani, M. Bitker and P. Viars

Is the vasoconstrictive effect of cyclosporine mediated by endothelin in kidney transplantation? A.84
C. Mouquet, A. Carayon, S. Ourahma, M.-O. Bitker and P. Viars

Renal blood flow and function relationship in recent renal transplantation in man A.85
L. Jacob, J. J. Chazalet, D. Payen, J. Bedrossian, P. Teillac and B. Eurin

13.40–15.10 Friday 14 May, 1993—Lèopold II A
Metabolism—General I (Oral session)

Effect of recombinant human growth hormone (HGH) on protein metabolism in surgical patients A.86
F. Carli, J. Anderson, M. Read and D. Halliday

Glycine and its metabolites during and after intrauterine YAG laser surgery A.87
M. J. Van Boven, P. E. Pendeville and F. J. Singelyn

Carbohydrate deficient transferrin: A new copredictor of alcoholism related postoperative complications? A.88
T. Heil, C. Spies, T. Neumann and C. Müller

Effects of diazepam additives on the mononuclear phagocytic system A.89
J. C. Catalá, J. A. Carrera, M. J. Iribarren, F. García-Pedrajas and J. L. Arroyo

Adrenocortical function: A clinical comparison of Etomidat-Lipuro® and Hypnomidate® A.90
A. Wiebalck, B. Vanacker, H. Van Aken, L. Sermeus, R. Bouillon and A. Amery

Isoflurane inhibits Ca^{2+}-induced insulin secretion from electrically permeabilised islets of Langerhans A.91
J. P. Desborough, P. M. Jones, S. J. Persaud and S. L. Howell

15.40–17.10 Friday 14 May, 1993—Astrid
Metabolism—General II (Oral session)

Exercise and malignant hyperthermia: Family investigations A.92
G. K. Ribbens, L. Rodet, J. Borsarelli, M. Aubert and P. J. Cozzone

Is Burkitt's lymphoma an etiology or a differential diagnosis of malignant hyperthermia? A.93
A. Lienhart, H. Deriaz, H. Desnault, J. P. Masini and E. Delva

ABSTR. NO.

Inhibition of increase of blood thromboxane concentration by acetylsalicylic acid after release of tourniquet in lower extremity operations A.94
R. Ojanen, S. Kaukinen, E. Seppälä, L. Kaukinen and H. Vapaatalo

The combined prophylactic administration of H1 and H2 receptor blockers in the prevention of protamine related haemodynamic effects and the relation between antihistaminics – leucocytes and pulmonary vascular resistance A.95
P. Durak, A. Özgök, H. Esen, Ö. Erdemli and S. Ebil

The relationship between cardiopulmonary bypass related immunologic effects and complement, thromboxane and leucocyte parameters A.96
P. Durak, A. Özgök, G. Saydam, A. Türkmen, Ö. Erdemli and S. Ebil

15.40–17.10 Friday 14 May, 1993—Lèopold II B
Clinical circulation—Blood preservation (Poster session)

Use of aprotinin during cytoreductive surgery of ovarian cancer A.97
F. Lequeau, J. L. Bourgain, D. Castaigne and M. Samama

Blood requirements reduction in orthotopic liver transplantation with aprotinin A.98
P. Monedero, J. Carrera, J. Catalá, F. Carrascosa and J. L. Arroyo

High dose aprotinin versus desmo-pressin acetate treatment in cardiac surgery A.99
F. Hidalgo, J. A. Páramo, J. C. Catalá, F. Carrascosa and P. Monedero

Aprotinin does not decrease surgical bleeding and could promote arterial thrombosis in the pig: A prospective randomized, blinded study A.100
C. M. Samama, E. Mazoyer, P. Bruneval, P. Bonnin, M. Bonneau, G. Pignaud, P. Viars, J. P. Caen and L. O. Drouet

Effects of recombinant-human erythropoietin on postoperative transfusion requirements in subjects undergoing major orthopaedic surgery A.101
P. P. Faris, M. Ritter, R. Abels, D. Gordon and r-HuEPO Surgery Study Group

Peroperative autotransfusion in emergency surgery for spine trauma A.102
B. Riou, S. Cavallieri, R. Roy-Camille and P. Viars

Effects of postoperative autotransfusion in spine surgery A.103
B. Riou, M. Guerrero, M. Arock, M. Ramos and P. Viars

Acute preoperative plasmapheresis during cardiac surgery A.104
G. Armellin, D. Pittarello, D. Penzo and G. P. Giron

10.40–12.10 Wednesday 12 May, 1993—Dynastie A
NEUROSCIENCES (ORAL SESSION)

Transcranial Doppler sonography: effect of propofol and thiopental in patients with brain tumors and brain injuries A.105
W. Schregel, C. Geißler, U. Bredenkötter and H. Schäfermeyer

Jugular bulb metabolic monitoring during hyperventilation in severe head trauma patients A.106
C. De Deyne, T. Vandekerckhove, J. Decruyedaere, J. Poelaert and F. Colardyn

Sufentanil increases intracranial pressure in patients with head trauma A.107
J. Albanese, X. Viviand, O. Durbec, B. Alliez and C. Martin

Cardiac function in aneurysmal subarachnoid haemorrhage A.108
N. Moulay, V. Mahé, A. Descorps-Déclère, C. Cosson and C. Ecoffey

External ventricular CSF drains infections A.109
V. Mahé, N. Kermarrec and C. Ecoffey

EEG-monitoring during defibrillator-implantation: effects of repetitive cerebral ischemia on electric brain activity A.110
C. Spies, S. Kraemer, T. Heil, T. Neumann and K. Reinhart

15.40–17.10 Wednesday 12 May, 1993—Lèopold II A
NEUROSCIENCES (POSTER SESSION)

Midazolam prevents ketamine-induced stimulation of cerebral metabolism A.111
J. Åkeson, S. Björkman and K. Messeter

Nitrous oxide induced neuronal depression: modification through benzodiazepine receptors A.112
M. Dzoljic, E. Geller, J. Rupreht, W. Erdmann and M. R. Dzoljic

Dexmedetomidine does not exercise its anesthetic action through GABA A.113
M. Salonen, J. Kendig, B. O'Connor and M. Maze

Differential effects of specific delta and kappa opioid antagonists on the bidirectional effect of naloxone in arthritic rats A.114
I. Cattaneo, V. Kayser and G. Guilbaud

Effect of morphine on a nociceptive flexion reflex in patients with postoperative pain A.115
M. Chauvin, F. Guirimand, P. Gauneau and C. Lebrault

Involvement of μ, δ, and κ receptors in the inhibition by intrathecal morphine of a C-fibre evoked reflex in the rat A.116
F. Guirimand, M. Strimbu, J. C. Willer and D. Le Bars

Isoproterenol reverses the MAC decreasing effect of esmolol in rats A.117
A. Perel, A. Shneider and W. Kohn

Effect of esmolol versus lidocaine on intracranial pressure and haemodynamic responses to laryngoscopy and intubation A.118
T. Samaha, P. Ravussin, C. Clacquin and C. Ecoffey

ABSTR. NO.

Effects of intrathecal meperidine (MP) fentanyl (FN) and lidocaine (LD) on somatosensory (SSEP) and cortical motor (CMEP) evoked potentials in humans A.119
S. Fernandez, J. Monells, J. M. Espadaler and M. M. Puig

8.40–10.10 Thursday 13 May, 1993—Astrid
LOCAL AND REGIONAL ANAESTHESIA (ORAL SESSION)

Slow-release effect of pH-adjusted bupivacaine: Pharmacokinetic demonstration A.120
D. Benhamou, J.-M. Malinowsky, V. Quinquis, P. Bourget and G. Couarraze

Lemakalim reverses ventricular conduction impairment induced by a large dose of bupivacaine in anaesthetized dogs A.121
J. E. de La Coussaye, J. J. Eledjam, P. Bruelle, P. Peray and A. Sassine

Motor blockade and absence of local nerve toxicity induced by liposomal bupivacaine injected into the axillary brachial plexus of rabbits A.122
F. J. Legros, N. Lafont, M. Donnay and J. Boogaerts

The effects of bupivacaine, mepivacaine and prilocaine on platelet aggregation A.123
N. Bayhan, M. E. Güzeldemir and H. Türkan

The effects of epidural and spinal anesthesia on the changes in the plethysmographic signal in the lower and upper limbs ... A.124
S. Preisman, I. Eldar and A. Perel

The effect of parenteral diclofenac and morphine on efficacy duration and height of blockade during continuous epidural bupivacaine 0.5 % A.125
D. Forbes, A. Binning and N. B. Scott

10.40–12.25 Friday 14 May, 1993—Dynastie A
LOCAL AND REGIONAL ANAESTHESIA (ORAL SESSION)

Nine years of clinical experience with 29 gauge spinal needles A.126
M. Dittmann, H.-G. Schäfer, F. Renkl and I. Greve

Incidence of post dural puncture headache in young adults by the use of the Sprôtte needle: 300 patients A.127
C. Descraques, G. Mion, Y. Auroy, B. Lenoir, B. Pats, B. Rouvier and J. P. Chabanne

Postdural puncture headaches are not related to the duration of spinal catheter placement A.128
N. Liu, A. Montefiore, N. Kermarec, L. Beydon and F. Bonnet

Epidural blood patch for treatment of postdural puncture headache A.129
P. H. Rosenberg, T. Taivainen, M. Pitkänen and M. Tuominen

Sequential spinal peridural anaesthesia for gynaecological surgery under laparoscopy A.130
S. Joos, R. Quintilla and R. Servais

Subarachnoid anaesthesia (SAA) and post-operative analgesia with bupivacaine (BV) plus fentanyl (FN) in geriatric patients A.131
D. Fernandez C. Castells, M. Rue, M. Bernaus and M. M. Puig

Fentanyl or buprenorphine side effects in spinal anaesthesia A.132
R. Foppoli, P. Lunghi, Z. Bonara, C. Mora and R. Stacca

PHARMACOLOGY

8.40–10.10 Thursday 13 May, 1993—Dynastie A
Neuromuscular blockers I (Oral session)

Comparison between double-burst stimulation and 50, 100 Hz tetanic fade during spontaneous recovery of vecuronium induced neuromuscular blockade A.133
M. J. Baurain, B. S. Dernovoi, A. A. d'Hollander and D. M. Schmartz

Reversal of vecuronium induced neuromuscular blockade: No effects of atropine administration timing A.134
M. J. Baurain, B. S. Dernovoi, A. A. d'Hollander and P. C. Bollen

Can repetition of high frequencies stimuli alter the value of 50 and 100 Hz tetanic fade during vecuronium induced neuromuscular blockade? A.135
M. J. Baurain, B. S. Dernovoi, A. A. d'Hollander and D. M. Schmartz

Does nicardipine potentiate the neuromuscular block of atracurium? A.136
J. E. Bazin, T. Gillart, A. Comte, C. Dubray and P. Schoeffler

Neostigmine antagonism of neuromuscular blockade induced by mivacurium, vecuronium and atracurium A.137
B. S. Dernovoi, M. J. Baurain, A. A. d'Hollander and P. C. Bollen

13.40–15.10 Thursday 13 May, 1993—Lèopold II A & II B
Neuromuscular blockers II (Oral session)

The pharmacokinetics of rocuronium in pediatric patients: A pooled data analysis A.138
C. Meistelman, P. Fiset, B. O'Kelly, J. Frossard, B. Plaud and C. Ecoffey

Priming of atracurium with magnesium A.139
E. Lampl and M. Dandoy

Supra-additivity between atracurium and vecuronium A.140
O. A. Meretoja, B. W. Brandom, T. Taivainen and L. Jalkanen

Concentration-effect relationship at the vocal cords and the adductor pollicis following rocuronium administration A.141

A NEW CLINICAL SCORE TO PREDICT DIFFCULT INTUBATION

Jean Arné, Pierre Descoins, Denis Bresard,
Jacques Ariès, Jacques Fusciardi

Department of Anaesthesia and Intensive Care,
University Hospital of Poitiers, Poitiers, France

Background and goal of study: The prediction of difficult intubation (DI) is very important in anaesthesia to reduce the morbidity related to failed intubation. The multifactorial index previously described [1-3] failed to predict DI in at least a quarter of the cases. The goal of this study was to test a new clinic score in an attempt to increase the sensitivity of prediction.

Materials and methods: 295 grown-up patients undergoing ETN or stomatological surgery were included in a prospective study. Our score was established by the assignment of points (0, 3, 5 or 7) depending on the degree of reach of seven factors : presence or not of a pathology known to be associated with DI, presence or not of clinic signs of airway's pathology, interincisive gap and mandible's luxation, thyro-mental distance, normal or short and broad neck, head and neck movement, and Mallampati's test. The intubation was defined as difficult when it required particular technics (special laryngoscope, fiberoptic intubation).

Results and discussion: The incidence of the DI was 8%; the best predicting level of the score has been determined at 11 using the "Receiver Operating Characteristic curves". A score higher than 11 foretells a DI with a sensitivity of 96%, a specificity of 90%, a positive predictive value of 46%, and a negative predictive value of 100%. The sensitivity of this score is better than with the multifactorial index of Wilson [1] (75%), Pottecher [2] (70%) and Frerk [3] (81%), with the same specificity. Moreover, these results are related to an ETN surgical population where the incidence of DI is higher than in general surgery : this fact induces a decrease in sensitivity of any test as compared to populations with a lower incidence of DI. Incidence of DI was lower in previous studies (1.5-6%) [1-3].

Conclusion: The sensitivity of the multifactorial clinic score seems to be improved when clinic signs of airway's pathology, and illness associated with DI are included. This conclusion remains true when a population with a high incidence of DI is concidered.

A.2

AN AUDIT OF THE INCIDENCE AND COSTS ASSOCIATED WITH POST OPERATIVE NAUSEA AND VOMITING (PONV) FOLLOWING MAJOR GYNAECOLOGICAL SURGERY IN AN INPATIENT POPULATION.

Morris RW[1], Ernst E, Greaves DJ, Layfield DJ,
Michael RF
[1]Princess of Wales Hospital, Bridgend, United Kingdom

118 inpatients, who had not received an anti-emetic in the 24 hours prior to major gynaecological surgery, were entered into a multicentre observational study to assess the incidence and costs associated with PONV. No restrictions were placed on the investigators' choice of anaesthetic agents.

For the first 24 hours after surgery detailed records of the incidence, frequency and resources used in treating PONV were collected by nurse observers not involved in caring for the patient. An emetic episode was defined as a single vomit or dry retch or any number of continuous vomits or retches. To count as a new episode, vomits or retches had to occur at least one minute after a preceding episode. Material costs were derived using mean cost data from all centres. National (UK) hourly rates for medical staff were used to value time spent treating patients and full NHS prices were used for anti-emetic drugs. These costs were used to estimate the mean cost of PONV per patient and the mean cost per emetic episode

Results: 45% of patients had an abdominal hysterectomy, 22% a laparotomy, 16% a vaginal hysterectomy and 17% some other major gynaecological surgery 40(34%) patients experienced PONV in the recovery room and spent a mean (S.D.) of 74.4 (35.9) minutes in recovery compared to 56.5 (26.4) minutes for patients not experiencing PONV in recovery ($p < 0.01$).

Over the full study period 98 (83%) patients experienced PONV and 75 (64%) had at least one emetic episode. The latter patients had a mean (S.D.) of 4.5 (3.6) emetic episodes per patient. Table 1 summarises the costs per patient of PONV and cost per emetic episode.

Table 1: Mean Cost of PONV per Patient

	N	Lab	Mat (£)	Drug (£)	Tot (£)
All Patients	117*	2.52	0.38	0.48	3.38
Patients with PONV	97	3.01	0.45	0.56	4.02
Patients with emesis	74	3.53	0.54	0.61	4.68
Cost per emetic episode		0.75	0.11	0.19	1.05

*One patient had emesis, but had missing resource data

Conclusion: This study suggests PONV frequently occurs after major gynaecological surgery giving rise not only to patient discomfort but also to additional NHS costs.

A.3

ANESTHESIA FOR PATIENTS ≥90 YEARS OF AGE IN EMERGENCY HIP SURGERY.

Eleftheriadis S.; Kuppe H.; Klotz K.-F.; Schmucker P.

Department of Anesthesiology, Medical University of Luebeck, Germany

INTRODUCTION: Persons ≥ 90 years of age represent a rapidly growing segment of our population. Progress in surgery, anesthesia and the more liberal use of perioperative invasive monitoring increases the surgical rates in these patients (1).

PATIENTS AND METHODS: In an 18 months period, 37 Patients (34 women) ≥ 90 years of age underwent surgical correction of a fractured neck of femur. Preoperative risk factors included: Hypertension (54%), cardiovascular (67%), respiratory (43%) and cerebrovascular disease (32%). Prior to induction of anesthesia a radial arterial and a jugular vein catheter were inserted; in 12 patients a pulmonary arterial catheter too. Thirty-one patients received a spinal and six patients general anesthesia.

RESULTS: The baseline cardiac output (CO) was 4,9±1,2 l/min.. Through subtle volume loading and vasoactive drugs the CO and the arterial blood pressure were maintained stable throughout the operation. The mean blood transfusion was 535 ml/patient. Due to increased O_2-Consumption, O_2-insufflation was necessary in the immediate postoperative period. Hospital deaths were 5 (13,5%).

CONCLUSIONS: The ≥ 90 years aged, with his limited reserves, requires our intensive interdisciplinary attention. The exact preoperative evaluation of the patient, precise intraoperative monitoring, maintenance of hemodynamic stability and normoxaemia as well as optimal postoperative care, are the important prerequisites for successful handling.

1.Warner MA, Hosking MP, Lobdell CM, Offord KP, Melton LJ: Surgical procedures among those ≥90 years of age: A population based study in Olmsted Country,Minnesota,1975-1985.

A.4

A SURVEY OF SLEEP PROBLEMS IN SURGICAL PATIENTS.

L. Beydon, A. Rauss, F. Lofaso,
A. Harf, F. Bonnet.

Dept of Anesthesia. Henri Mondor Hospital,
94010 Créteil - France.

Insomnia is a common complain in surgical patients. In order to appreciate its prevalence and promoting factors we conducted a questionnaire survey in 176 consecutive patients who had elective surgery, in three surgical departments (general, orthopedic, vascular). Three questionnaires were filled out: 1) the day before surgery, 2) the day of discharge, 3) 15 days after discharge. They included 58 questions about subject personality, usual and postoperative sleep profile and sleep quality, intensity of hospital disturbances and pain, physical fitness, previous surgical experience. Answers were given in a quantitative form. 89.2 % of patients (52.3 men, 51.9 ± years, 80 % ASA I-II, hospital stay: 9.9 ± days) completed the whole study. 42 % received hypnotic drugs the night before surgery, 35.2 % were hospitalized in single room, 16 % stayed in ICU postoperatively, 42 % of patients needed more than 4 days to recover sleep, postoperatively. Complain about night cares and noise were noted in 23 and 17 %. Sleeping pills were taken by 18, 38, and 27 % of patients, in day life, after surgery and 15 days after discharge (D_{15}) respectively. Pain at D_{15} was noted in 47 % and requiring analgesics in 33 %. Factor analysis showed that self-rated postoperative insomnia was related to three major variables: pain (p=0.0002), a poor sleeper profile in day life (p=0.003) and the level of anxiety facing surgery (p=0.04). Environmental disturbance, psychological profile, previous surgical experience did not participate to the level of postoperative insomnia. Those who experienced poor postoperative sleep were those who still did not sleep well, 15 days after discharge. In conclusion, the complain of poor sleep in the early postoperative period is frequent. Pain represents one major etiologic factor for insomnia. Improving analgesic therapy probably could improve sleep and comfort at night in the early postoperative period.

A.5

INDICATIONS FOR CORONARY REVASCULARISATION IN VASCULAR SURGICAL PATIENTS.

Marilyn Gosgnach, Pierre Coriat,
Marie-Hélène Fleron, Michèle Bertrand, Pierre Viars.
Department of Anesthesiology, CHU Pitié-Salpêtrière,
University Paris VI, Paris, France.

Background: In patients undergoing vascular surgery preoperative coronary angioplasty (PTCA) or bypass graft surgery (CABG) might reduce the perioperative risk and more importantly improve the long term survival of these high risk individuals (1). Accordingly, one of the main goal of the preoperative assessment is to identify the patients in whom a coronary intervention is needed prior to surgery. The aim of this study is to compare the percentage of indications for coronary intervention in patients undergoing surgery for occlusive disease of the abdominal aorta (O.D.A.) vs abdominal aortic aneurysm (A.A.A.) vs carotid endarterectomy (C.E.).

Methods: All patients, aged between 55-71 years, admitted to our institution during 1992 for abdominal aortic or carotid surgery were included in this study. A routine coronary angiography was performed as part of the preoperative assessment in these 127 consecutive patients.

Results: The prevalence and the severity of coronary artery stenoses are shown in the table according to the type of the vascular disease.

	O.D.A.	**A.A.A.**	**C.E.**
n	40	41	46
Mean age	62 yrs	65 yrs	63 yrs
Clinical CAD	n = 10	n = 13	n = 14
At least one coronary artery stenosis			
> 50 %	n = 21	n = 30	n = 32
> 70 %	n = 11	n = 28*	n = 22*
Coronary steal prone anatomy			
n	n = 3	n = 5	n = 6
indication for myocardial revascularisation			
n	n = 1	n = 11*	n = 11*
PTCA/CABG	1/0	7/4	2/9

* $p < 0.005$ vs 0.D.A.

Conclusion: Coronary revascularisation was indicated in one quarter of patients scheduled for A.A.A. or C.E., but only in 3 % of patients with O.D.A.. This should be taken into account for the preoperative management of these patients.

References: (1) Reul G. et al : The effect of coronary bypass on the outcome of peripheral vascular operations in 1093 patients. J. Vasc. Surg., 3 : 788-798, 1986.

A.6

DOES ROUTINE PREOPERATIVE CORONARY ANGIOGRAPHY MODIFY OUTCOME AFTER AORTIC SURGERY ?

Marilyn Gosgnach,Michèle Bertrand, André Pironkov,
Pierre Coriat ,Pierre Viars
Department of Anesthesiology, CHU Pitié-Salpêtrière,
University Paris VI, Paris,France

Background and goal of the study: Early studies in vascular surgical patients with CAD identified by coronary arteriography (CA), suggested that coronary intervention (PTCA or CABG) could reduce cardiac morbidity following aortic surgery (1). The aim of this study was to determine whether this approach actually decreases the risk for perioperative coronary complications: myocardial ischemia or infarction (MI).

Material and methods: 111 Consecutive (61-70 year old) patients scheduled for aortic surgery were prospectively studied a comparison between the incidence of postoperative cardiac complications in patients admitted during the year 1990 (group 1) who had only a standard clinical preoperative work up and in patients admitted during 1991 in whom a CA was part of their routine preoperative evaluation (group 2) was made.

Results:

	group 1 : 1990	group2 : 1991
n	57	54
PTCA	0	7 (6 successful)
CABG	0	7
perioperative ischemia	14/57	12/51*
postoperative MI	1	1

* aortic surgery was not performed in 2 patients who underwent CABG and in one patient who died before the coronary intervention.

Conclusion: Routine preoperative CA did not lead to an increased mortality or morbidity. Although routine preoperative CA resulted in performing coronary intervention in 14 % of the patients, this invasive preoperative screening test did not reduce cardiac morbidity following the subsequent aortic surgical procedure. Further studies are needed to determine whether this approach improves long term survival of these high risk individuals.

A.7

OUTCOME FOR PATIENTS IN INTENSIVE CARE WITH ACUTE RENAL FAILURE REQUIRING DIALYSIS

Ellen Ejlersen, Maiken Brit Jensen, Kirsten Eliasen,

Departments of Anaesthesia and Nephrology, Herlev Hospital, University of Copenhagen, Denmark

Background and goal of study: Acute renal failure (ARF) carries a high mortality. Most reports cite the mortality to be in the range 50-90%. Despite improvement in the management of critically ill patients the mortality has failed to improve through the last 20-30 years. The purpose of our study was to review the experience of ARF treated in a single ICU, to evaluate if mortality has changed from early to late period of study, and to identify factors which might have influenced outcome.

Materials and methods: All ICU patients with ARF needing dialysis in the period 1977-1989 were included. The study was retrospective.

Results and discussion: Of the 167 patients included, 129 were men and 38 women, median age was 60 y (range 14-82). 58% developed ARF complicating surgery. 42 patients (25%) survived, two of whom continued chronic dialysis treatment. Age above 60 y ($p<0.02$), requirement of mechanical ventilation ($p<0.0005$), administration of inotropic drugs ($p<0.0005$), and increased serum bilirubin levels ($p<0.005$) had negative influence on survival. Mortality increased significantly from 63% during the early period (1977-85) to 84% during the late period (1986-89), probably due to selection bias with a more morbid population being treated in the later years.

Conclusion: One quarter of ICU patients with ARF requiring dialysis survived. Of the proportion of patients requiring mechanical ventilation only 20% survived. The survival rate was further reduced to 11% for patients who developed jaundice and required vasopressor therapy in addition to mechanical ventilation.

A.8

A NATIONAL DATABASE FOR INTENSIVE CARE MEDICINE IN SWEDEN.

Mats Karling

Department of Anaesthesia and Intensive Care Medicine, University of Umeå, Umeå, Sweden.

Background: Intensive care is an expensive area of medical care which is associated with high mortality. In the United States (US) the cost of intensive care is estimated to be around 1% of GNP. In Sweden the cost is around one half of that in the US. Mortality is about 20% in the intensive care unit (ICU) and around 30% at one year. Validated methods for outcome prediction and quantitation of care exist (1, 2). These can be used to compare the results and costs from different centres (3). This paper describes the Swedish national data base system for intensive care which will be operational from Jan. 1st 1993.

Patients and methods: Data from all patients admitted to a member ICU, with the exception of those with uncomplicated postoperative course, are collected in a local database. The following variables are registered; *First 24 hours:* APACHE II, route of admission, demographic data. *Daily:* TISS, major therapeutic interventions and number of ICU staff for each shift. *At discharge:* patient's status and diagnoses. The contents of the local database are sent to a central database every three months. This database retrieves deaths from the Swedish Population Register (SPAR) every six months. Each participating centre receives a report comparing their mortality ratio according to APACHE II predicted outcome, with the average ratio and the ratio within the same type of unit.

Discussion: At present, 60 of 96 ICU-s participate. This includes all major hospitals in Sweden. The database will make it possible to get an overview of ICU use in Sweden. APACHE II will be a tool for the comparison of results and a standard for quality assurance. The resources needed to obtain these results will be measured from TISS and ICU staffing. The value of certain expensive therapeutics such as ECMO, plasmapheresis and haemodialysis, can be analysed. It is estimated that the size of this database will allow detection of changes in medical practice.

A COMPARAISON OF MIDAZOLAM AND MIDAZOLAM PLUS FENTANYL FOR COLONOSCOPY.

Hervé Dupont, Jean-Baptiste Nyarwaya, Kamran Samii

Département d'Anesthésie-Réanimation
Université Paris Sud,Hôpital de Bicêtre
94275 Le Kremlin-Bicêtre cedex
France

***Background and goal of study*:** Colonoscopy (C) is a painful procedure usually performed with sedative drugs (1). The addition of opioids to sedative drugs may increase the tolerance of the procedure (2) but increases the risk of respiratory depression (3). The purpose of this prospective, double blind, randomized study was to evaluate the benefit and risk of the addition of fentanyl (F) to midazolam (M) during Colonoscopy.

Materials and methods: After ethical approval, sixty patients, ASA 1 to 3, were randomized to receive M+placebo (MP group) or M+F (MF group). Mean arterial blood pressure (MAP), heart rate (HR), respiratory frequency (RF) and pulse oxymetry (SpO$_2$) were monitored every 10 min during C and in the recovery room during 90 min. Sedation score (S) from 0 to 4 and endoscopy conditions score (EC) from 0 to 2 were evaluated. Sedation was induced with M=2mg and F=1µg/kg. Additional boluses of M=1mg were injected with a 5 mg limit total dose in order to reach an EC score of 2. In case of failure, another F=1µg/kg was given. Finally, Propofol (P) was used (up to 1mg/kg), to reach an EC score of 2. If SpO$_2$ < 90%, RF < 12/min or S score of 4 were observed, 3L. mn^{-1} O_2 was administered under spontaneous or assisted ventilation. Statistical analysis included ANOVA for quantitative data and Chi-Squares test with Yates' correction for categorial data.

Results and discussion: Both groups were comparable except for age (57.8±15.7 yr vs 47.6± 13.9 yr, p=0.01) and MAP (110±18 mmHg vs 100± 14 mmHg, p=0.02) for MP and MF group respectively. There was no difference in S scores between groups, but EC scores were higher in MF group (p=0.01). In the recovery room, abdominal pain was lesser in MF group (p=0.02). In the MP group, it was necessary to use more M (p=0.02), P more often (p=0.03) and to higher doses (p=0.04). The frequence of a deacrease in SpO$_2$ >5%, the lower value of SpO$_2$ and the maximum deacrease variation in SpO$_2$ were significantly different between MF and MP group (69 vs 31%,p=0.03, 92±5% vs 95±3%,p=0.01, -6±5% vs -3±2%,p=0.001). After P, apneas were more frequent in MF group (p=0.01).

Conclusion: We conclude that the addition of F to M entails better EC score, less P general anesthesia, less abdominal pain but an increased respiratory depression.

A.10

EVALUATION OF SACCADIC EYE MOVEMENTS AS AN OBJECTIVE TEST DURING RECOVERY FROM ANESTHESIA

Olivier Paut, Jean Louis Vercher, Olivier Blin, Daniel Mestre, Jean Camboulives

Department of pediatric anesthesiology and intensive care, La Timone University Hospital, Marseille, France

Background and goal of the study: Saccadic eye movements have been used to assess residual effects of anesthetics (1), but there is no data concerning comparison of this assessment method with other psychomotor tests during recovery from anesthesia. The aim of this study was to evaluate saccadic eye movements measurement as an objective test of recovery from anaesthesia, in comparison with subjective and objective tests of reference.

Material and methods: This randomized, double blind, crossed over, placebo controlled study was approved by the University ethical commitee. After informed consent given, 8 healthy, male volunteers, aged 25 years, weighting 76 kg were included. They received 0.15 mg.kg^{-1} IM of midazolam (MDZ) or placebo (PLA) during two experimental sessions separated with at least one week of interval. Psychomotor function was assessed before induction (t0) and 30 (t30), 60 (t60), 120 (t120), 180 (t180), 240 minutes after injection (t240), using a battery of tests including: Visual analogic scales (VAS), Choice reaction timer (CRT) and saccadic eye movements (SEM) measurements with electrooculogram detection, allowing registration of SEM parameters [ie latency, peak saccadic velocity (PSV), duration]. Blood samples were obtained at the same study time in order to determine plasma concentrations of MDZ. Statistical analysis was made using one way ANOVA for repeated measures and Dunnett's test.

Results and discussion: Main results are shown in table I. In the PLA group, there is no difference between each study evaluation concerning saccadic parameters and VAS. On the other hand, there is a significant difference during time concerning CRT, with a decrease of performance from t60 to t180 (ANOVA p < 0.01, Dunnett's test p < 0.05). In the MDZ group, there is a significant difference for CRT from t30 to t180. Saccadic parameters are significantly different from t30 to t120 (latency, duration) and from t30 to t180 for PSV (ANOVA p < 0.0001, Dunnett's test p < 0.05).

VAS assessment showed that only 5 items were significantly different from t30 to t120 (drowsy, on form, tired) at t60 and t120 (clumsy) or only at t120 (woolly).

Conclusion: These results show that SEM measurement is a good tool for assessing residual effects of anesthetics during recovery from anesthesia. We found this test more reliable and robust than CRT, chosen as a test of reference. Saccadic eye movements are altered by MDZ used with premedicant doses, and a 3 hours delay is needed for a complete psychomotor recovery. Subjective assessment using VAS is not a reliable method, subjects tending to underestimate their status in the early study period, in the MDZ experimental session.

Table I: Time course of psychomotor performance in the placebo group (PLA) and midazolam group (MDZ). *p<0.05 (Dunnett's test, after ANOVA).

		t0	t30	t60	t120	t180	t240
CRT	MDZ	32,9	90,9*	70,3*	51,7*	42,9*	36,2
10^{-2}s	PLA	33,7	34,8	35,8*	37,7*	36,1*	35,2
PSV	MDZ	301,3	160,4*	180,3*	237,7*	266,5*	293,8
	PLA	301,8	297	300,6	290,1	296,9	292,5

ALIZAPRIDE DOES REDUCE PAIN ON INJECTION OF PROPOFOL : COMPARISON WITH LIDOCAINE.

ZAOUK G., M.D., GILBART E., M.D., DUBOIS A., M.D., JACOBS D., M.D., BALATONI E., M.D.

University Hospital Center A.VESALE,
MONTIGNY-LE-TILLEUL - BELGIUM.

Background and goals of the study: Propofol (P) is an intravenous hypnotic drug with many suitable characteristics. Pain due to its injection is a well recognized problem. Lidocaine (L) has been used with efficacy to reduce the incidence of pain on injection of P (1). Alizapride (A) is a benzamide derivative structurally related to procainamide known to be an effective anti-emetic drug in cytotoxic- and anesthetic-induced vomiting. The purpose of this study was to evaluate the efficacy of A compared with L in reducing pain on injection of P.

Materials and methods: After approval by local Ethics Committee, we studied 300 patients (ASA 1-2) scheduled for various elective surgical procedures. Subjects were allocated randomly to 3 groups (N=100) and received, on a double-blind basis, either 1 ml 0.9% NaCl or 1 ml 1% L or 1 ml A (25 mg) immediately before injection of P. The pain score used was : 0 = no pain even on demand; 1 = complaint of pain when asked after 50% of the total dose; 2 = spontaneous complaint before 50% of the total dose; 3 = pain with arm retraction, grimacing or both.

Results: The 3 groups were comparable in their sex, age, weight and ASA distribution (ANOVA, Chi-squared and Fischer tests). Both L and A significantly reduced pain on injection of P when compared with saline, but L reduced it more than A (Table 1).

TABLE 1

score :	0	1	2	3
NaCl :	22	17	20	41
A :	44	34	12	10
L :	82	16	0	2

Overall Kruskall-Wallis test : p=0.0001
Wilcoxon rank sum test for individual
comparisons : p=0.0001 NaCl vs L
p=0.0001 NaCl vs A
p=0.0001 A vs L

Discussion: In conclusion, A can be an useful alternative for reducing pain on injection of P in short surgical procedures, especially when antiemetic properties are needed, as in outpatient anesthesia.

ONDANSETRON 4 mg VS DROPERIDOL 1.25 mg IN THE PROPHYLAXIS OF POSTOPERATIVE NAUSEA AND VOMITING AFTER ALFENTANIL-SUPPLEMENTED INHALATION ANAESTHESIA

Eli Alon, Philipp M. Lenzlinger, and Thomas Pasch

Department of Anaesthesiology, University Hospital, Zurich, Switzerland

Introduction: Ondansetron, a selective 5-HT_3 receptor antagonist, has recently been shown, in a dose of 8 mg, to be superior to droperidol 1.25 mg in preventing postoperative vomiting (1). There are indications that a dose of 4 mg of ondansetron may be just as effective in reducing postoperative nausea and vomiting as a dose of 8 mg (2). The aim of this study was to evaluate the efficacy and the adverse effects of 4 mg ondansetron in the prevention of postoperative nausea and vomiting compared to droperidol in patients undergoing surgery with inhalation anaesthesia supplemented with alfentanil.

Methods: Following institutional approval, 40 ASA physical status I and II women scheduled for minor gynecological surgery gave informed consent to participate in this randomized, double-blind comparative study. Five minutes before induction of general anesthesia, 20 patients received a single intravenous (IV) dose of 4 mg of ondansetron and the remaining 20 received 1.25 mg droperidol IV. Anesthesia was induced with 2.1 - 4 mg/kg of thiopental and 0.1 mg of alfentanil IV and maintained with 65% nitrous oxide and 1.5%-3% enflurane in oxygen. On pain stimuli another 0.2 - 0.4 mg of alfentanil were given. Total effective antiemetic response was defined as the absence of nausea and vomiting for 24 hours postoperatively. The incidence of nausea, vomiting and the number of patients showing total antiemetic response as well as the incidence of adverse effects were compared with the chi^2 - test and $p < 0.05$ was considered significant.

Results: Patients were similar with respect to age, height, body weight and total anaesthetic agents received. Duration of anaesthesia and the time for awakening was not significantly different among the groups. Postoperatively 7 out of 20 patients (35%) given 4 mg of ondansetron and 3 out of 20 patients (15%) with droperidol vomited (statistically not significant). The incidence of nausea was 55% (11/20) in the ondansetron group, and 20% (4/20) in the droperidol group ($p < 0.05$). 16 patients (80%) in the droperidol group and 8 patients (40%) in the ondansetron group showed a total effective antiemetic response ($p < 0.05$). Postoperative sedation and well-being scores did not differ significantly among the groups.

Discussion: A recent study (1) showed that ondansetron in a dose of 8 mg given preoperatively was superior to 1.25 mg droperidol in reducing postoperative vomiting. Our results show that 4 mg ondansetron was inferior to 1.25 mg droperidol given preoperatively in reducing nausea and vomiting after alfentanil-supplemented general anesthesia for minor gynecological surgery.

A.13

DOUBLE-BLIND COMPARISON OF ONDANSETRON, DROPERIDOL AND SALINE FOR PREVENTION OF NAUSEA & VOMITING AFTER ORTHOPAEDIC SURGERY

TJ Gan, R Collis, M Hetreed

Department of Anaesthesia, Royal National
Orthopaedic Hospital, Stanmore, Middlesex, UK

Background and goal of study: The incidence of postoperative nausea and vomiting (PONV) is as high as 83% after major orthopaedic surgery.[1] Ondansetron (O), a selective 5HT-3 antagonist, is suggested to be superior to other antiemetics in preventing PONV. This study compared its efficacy against droperidol (D) and saline (S) in patients after orthopaedic surgery.

Materials & methods: 93 ASA 1 & 2 patients undergoing hip or knee replacements, or femoral resections, received a standardised, combined epidural (10 ml 0.5% plain bupivacaine) and general (20 mg temazepam premedication, 2.5 mg/kg propofol induction, 66% nitrous oxide in oxygen, 2% enflurane, breathing via laryngeal mask) anaesthesia. At the end of surgery they were blindly randomised to receive either 1.25 mg D, 4 mg O or 0.9% saline. These were given intravenously over 10 mins in a 25 ml bag previously prepared by the pharmacy department. A Nausea and Vomiting chart was recorded by the nursing staff hourly for 24 hours. Side effects and administration of rescue antiemetic (10mg metoclopramide) were also recorded.

Results:

	n	no symptoms (%)	nausea (%)	vomiting (%)
O	33	21 (64)	7 (21)	5 (15)
D	28	17 (61)	7 (25)	4 (14)
S	32	9 (28)	8 (25)	15 (47)

Length of operation, weight, age and gender were similar between groups. Both O & D were superior to S in preventing PONV ($p<0.01$) though no significant difference was seen between them. However, metoclopramide was demanded by 34%, 29% and 9% of S, D and O patients respectively (D vs O $p<0.05$). Side effects from O & D were minimal.

Conclusion: Although O & D were equally effective in suppressing PONV, the reduced requirement for metoclopramide suggests that O provides greater subjective benefit.

A.14

COMPARISON OF ONDANSETRON, METOCLOPRAMIDE AND DROPERIDOL FOR THE PROPHYLAXIS OF EMETIC SYMPTOMS AFTER GYNECOLOGICAL LAPAROSCOPIC PROCEDURES

Christine Geiger, Ottmar Kick, Hubert Böhrer, Johann Motsch
Eike Martin
Department of Anesthesiology,
University of Heidelberg, Heidelberg, Germany

Background and goal of study: Nausea and vomiting is a common problem after gynecological laparoscopic procedures. We evaluated the prophylactic efficacy of ondansetron, a selective 5-HT_3 antagonist in comparison to metoclopramide and droperidol.

Materials and methods: 60 ASA 1 patients, scheduled for gynecological laparoscopic procedures were randomly assigned in a double blind manner to receive either 8 mg ondansetron, 10 mg metoclopramide or 1.25 mg droperidol 2 min prior to induction. All patients were premedicated with 7.5 mg midazolam orally 45 min prior to induction. Anesthesia was induced with propofol 2.0-2.5 mg/kg, fentanyl 0.1 mg, succinylcholine 1 mg/kg and vecuronium 0.6 mg/kg. Anesthesia was maintained with 70% nitrous oxide in oxygen and isoflurane. An orogastric tube was placed after intubation and removed prior to extubation.The patients were followed up for emetic symptoms for 24 hrs. Data were analyzed using Chi-square tests, with $p < 0.05$ considered statistically significant.

Results and discussion: Patient characteristics and main results are listed in the table.

Parameter	Ondansetron	Metoclopramide	Droperidol
Number of patients	20	20	20
Age (yrs)	32±9	29±6	35±9
Duration of surgery (min)	30±21	31±25	21±11
Duration of anesthesia (min)	59±21	59±25	49±14*
Nausea (n)	1	3	2
Vomiting (n)	0	2	3

* = $p < 0.05$

Our anesthetic technique, which is considered to be associated with relatively few emetic sequelae, led to a low incidence of postoperative nausea and vomiting in all of the three study groups. The absence of vomiting with ondansetron was not statistically different in comparison to metoclopramide or droperidol.

The duration of operation, significantly shorter in the group treated with droperidol, did not show any correlation with the incidence of postoperative nausea and vomiting. Three of the patients treated with ondansetron spontaneously reported about an astonishing well-being after recovering from anesthesia.

Conclusion: We conclude that ondansetron given prophylactically prior to induction of anesthesia is a potent antiemetic agent without major side effects. It may not be superior to metoclopramide or droperidol in the prevention of vomiting after gynecological laparoscopic procedures.The euphorising effect of ondansetron seen in some patients needs further investigation.

A.15

CLINICAL EVALUATION OF THE CALIBRATION OF NONINVASIVE CONTINUOUS BLOOD PRESSURE MEASUREMENT DEVICES BY MEANS OF OSCILLOMETRIC BLOOD PRESSURE MEASUREMENTS.

Jan R. de Jong, Henk H. Ros, Jaap J. de Lange

Department of Anaesthesiology, Free University Amsterdam, the Netherlands

Background and goal of study: in recent years three types of non- invasive (semi-) continuous blood pressure measurement devices have entered the market. The Finapres, which uses a volume clamp technique, the Cortronic, which uses brachial artery pulsations, and the N-Cat which uses radial artery tonometry to determine the blood pressure. The latter two devices use oscillometrically determined blood pressure measurements from the upper arm to calibrate their continuous blood pressure measurements. The goal of our study was to determine whether oscillometric blood pressure measurement is an appropriate technique for calibration of noninvasive continuous blood pressure measurement devices.

Materials and Methods: in 11 patients (5 with Cortronic and 6 with N-Cat) Noninvasive blood pressure was measured on one arm, intra arterial blood pressure on the other arm. After each calibration sequence the first calibrated noninvasive analog waveform was recalibrated against the corresponding intra arterial waveform. For each recalibration this resulted in a multiplication factor (m.f.) for correction of differences between the systolic - diastolic amplitudes, and in a constant for bringing the two waveforms up to the same level. In both the Cortronic and the N-CAT group the median and the 2.5th and 97.5th percentile limits of agreement (1) were determined for the multiplication factor and for the constant. Also the correlation coefficient of the multiplication factor and the constant was determined.

Results and discussion: in the Cortronic group 154 calibrations were analyzed, the median and limits of agreement for the multiplication factor were: 1.04, 0.43 and 1.42 and for the constant: -10.7, -69.3 and 36.8 mm Hg. The correlation coefficient was R = 0.91. In the N-CAT group 93 calibrations were analyzed, the median and limits of agreement for the multiplication factor were: 0.72, 0.37 and 1.37 and for the constant: 20.1, -31.4 and 39.2 mm Hg. The correlation coefficient was R = 0.87. Our method of analyzing the calibration measurements is new and it provides a quantitative description of the effect a calibration mismatch will have on the subsequent continuous measurements in the event of blood pressure changes. A m.f. > 1 means that a certain blood pressure change will be under estimated. A m.f. < 1 means that it will be over estimated.

Conclusion: We conclude that the wide range of the limits of agreement for both the m.f. and the constant measured during anaesthesia and surgery in two different devices casts serious doubt on the appropriateness of the oscillometric blood pressure measurement as a calibration method for noninvasive blood pressure measurement devices.

A.16

TECHNICAL ASPECTS OF JUGULAR BULB OXIMETRY

Cathy De Deyne, Jan Poelaert,
Johan Decruyenaere, Francis Colardyn

Department of Intensive Care, University Hospital,
Ghent, Belgium

Background and goal of study: Jugular bulb oximetry has become more and more important in monitoring ICU patients suffering from neurologic crises. Nevertheless, the technical problems resulting in insufficient reliability of the oximetry system still remain. In this paper we want to describe the possible technical adaptation in order to improve the reliability.

Methods: Retrograde catheterization of the internal jugular vein (by the Seldinger technique) is performed using a 5F introducer sheeth (length 10 cm). After in vitro calibration, the 4F opticath is introduced 13-15 cm into the sheeth until its tip is located in the jugular bulb as confirmed by fluoroscopy. During the entire monitoring time both the oximetry catheter and the introducer sheeth are continuously flushed with a heparinized solution.

Results and discussion: Using this particular setting, we analyzed the reliability of the oximetry catheter. For this purpose, 6 hourly data of 40 patients with jugular bulb oximetry during a mean course of 96.6 h, were analyzed (linear regression) by comparing the saturation values displayed by the oximetry monitor with those measured by cooximetry (Corning 2500). The correlation coefficients between saturations obtained by the direct measuring technique and cooximetry remained surprisingly high during the whole time period (r=0.987 immediately after insertion, r=0.974 during the first 24h, r=0.934 for the compiled data).

Conclusions: The jugular bulb oximetry system described seems accurate and reliable. We are furthermore convinced that the use of an "introducer" system provides the necessary stability for the extremely flexible 4F oximetry catheter and could explain the good reliablity of the whole system.

A.17

IS CORRELATION OF ARTERIAL AND END-TIDAL CARBON DIOXIDE PRESSURE DURING INHALATION ANAESTHESIA BETTER WITH LARYNGEAL MASK AS COMPARED TO FACE MASK?

D. Ivens and C. Verborgh

Department of Anaesthesiology, Free University of Brussels Medical Centre, Brussels, Belgium

Aim of this study was to compare $PaCO_2$ and $PetCO_2$ differences and correlation in patients undergoing minor surgery during inhalation anesthesia with face mask (FM) and Guedel airway (n=9) or laryngeal mask (LM)(n=9). Induction of anesthesia consisted of propofol 2 $mg.kg^{-1}$ i.v., while anesthesia was maintained with isoflurane in a O_2/N_2O mixture (FiO2=0.4) delivered trough a circle system of a CICERO respirator. $ETCO_2$, sampled at the proximal connector (LM) and between mask and elbow-piece (FM), was recorded at 4 different times. T1 : after 5 min of spontaneous ventilation, T2 : after skin incision, T3 : after 15 min surgery and T4 : after 5 min of 100% oxygen. At these times arterial blood samples were also obtained and analyzed. Other variables measured were respiratory rate (RR), minute volume (MV), heart rate (HR), mean arterial pressure (MAP), oxygen saturation (SaO_2). Statistical analysis included basic statistics. Wilcoxon signed rank test for comparison within groups and MWU-test for comparison between groups. A single regression analysis (y = ax + b) was performed and tested with ANOVA. RR was non-significantly different between the two groups, while MV was higher at T3 in the FM group. Observed $PetCO_2$ was significantly higher at T1 and T3 in the LM group as compared to the FM group, while $PaCO_2$ was non-significantly different. $P(a-et)CO_2$ was significantly higher at T1 in the FM group. Regression analysis with $PetCO_2$ as dependent variable and $PaCO_2$ as independent variable revealed a better correlation in the LM group at T1, T2 and T3 (Table). Regression on pooled data resulted in a correlation coefficient of 0.21 in the LM group and 0.62 in the FM group. Other variables were non-statistically different between the two groups. It is concluded that during isoflurane/N2O anesthesia correlation of $PaCO_2$ and $PetCO_2$ is better with a laryngeal mask as compared to a face mask.

A.18

CARDIAC OUTPUT (CO) MEASUREMENT : COMPARISON OF ESOPHAGEAL DOPPLER (ED) VS THERMODILUTION (TD)

JY Lefrant, JE de La Coussaye, G Aya, G Saïssi, JJ Eledjam.

Dept of Anesthesiology and Intensive Care University Hospital. 30029 Nîmes. France

Background and goal of study : TD is the "gold standard" method to measure CO in ICU patients but can lead to serious complications(1-2). ED can measure CO with the aid of a nomogram based on age, height and weight(3). The aim of the study was to determine the accuracy of CO measured by ED vs TD.

Material and Methods : Were included 20 sedated patients under mechanical ventilation in whom Pulmonary Artery Catheter (PAC) was required. Were excluded patients with esophageal or pharyngeal diseases or surgery, with coagulopathy, with arrhythmias or those aged less than 18 years.The esophageal probe was introduced in the esophagus to measure the maximum velocity of blood flow in descending aorta. ED-CO was the product of maximum velocity determined by nomogram, aorta diameter and heart rate. TD-CO were determined by a triplicate injection of 10 ml of cold saline solution. CO measurements were simultaneously performed in blinded fashion by 2 observers when determination of hemodynamic status was required. ED-CO was always performed by the same observer after training (9 patients).

Results and discussion : 14 males, 6 females (58 ± 18 years) entered the study. ED-CO could be determined in 19 of them (95 %). 130 measurements were performed in patients in septic shock (n = 12), acute pancreatitis (n = 3), or following cardiac (n = 2) or digestive (n = 2) surgery.Regression coefficient (r^2) was 0.82. Bland & Altman test is shown in figure 1. Sensitivity (power to detect change of CO > 10% in the same way) was 75% and serious pitfall (opposite change of CO between the 2 methods) was 1,6%. (2 values).

Conclusion : CO determined by ED seems to be accurate but requires trained operator.

A.19

CARDIAC OUTPUT DETERMINED FROM PULMONARY GAS EXCHANGE

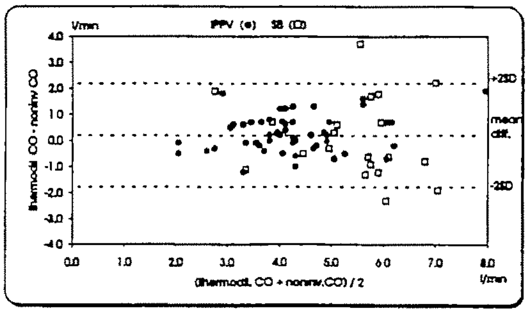
Barbro Österlund, Göran Johansson, Sebastian Reiz

Department of Cardiothoracic Anaesthesia & Surgery, University of Umeå, Umeå, Sweden.

Background and goal of study: A new system (1) by which cardiac output can be determined non-invasively (COniv) from carbon dioxide (CO2) elimination (VCO2), end-tidal CO2 tension (petCO2) and derived mixed venous CO2 tension (pvCO2) has been evaluated clinically. The goal of the study was to determine the accuracy and reproducibility of this gas exchange technique using thermodilution CO (COth) as the reference method.

Methods and patients: 35 patients were studied after institutional approval directly after cardiac surgery while sedated and mechanically ventilated (IPPV), as well as awake, extubated and spontaneously breathing (SB) 18 h later. Two COniv were obtained within 5 min during IPPV and SB. Simultaneously, 5 COth were recorded and averaged for comparison. The gas exchange system comprises a closed breathing circuit and measures oxygen uptake, VCO2 and petCO2. Periods of CO2 rebreathing are automatically implemented after a stable petCO2 level has been documented during 50 breaths and pvCO2 is extrapolated from the exponential rise of petCO2 during rebreathing. COniv is calculated as: VCO2/(petCO2-pvCO2).

Results and conclusions: 57 COniv could be obtained in the 35 patients during IPPV but only 21 in 18 patients during SB. The low number of measurements during SB was due to large variations in tidal volume and leakage around the mouth piece. Comparison of the techniques (IPPV+SB) is presented in the figure. Regression analysis showed: COniv = 0.72xCOth + 1.1, r = 0.71, p<0.05. Reproducibility of the two techniques was comparable.



We conclude that COniv had sufficient accuracy and reproducibility to be used for clinical decisions in sedated patients during IPPV whereas the performance during SB early after cardiac surgery was unacceptable.

A.20

PRESERVATION OF HUMIDITY AND HEAT OF RESPIRATORY GASES IN PATIENTS WITH MINUTE VENTILATION > 10 L/MIN.

Claude MARTIN, Laurent PAPAZIAN, Gilles PERRIN,
Pierre SAUX, François GOUIN
Department of Anesthesia and Intensive Care, Hôpital Nord and
Hôpital Sainte-Marguerite - Marseille - France

Background and goal of study : the study objective was to compare the thermic and humidification capacity of one Heated Humidifier System (Bennett Cascade 2 Humidifier) and two Heat and Moisture Exchangers (Pall Ultipor and Humid-Vent Filter, Gibeck) in intensive care unit patients submitted to minute ventilation > 10 l/min.

Materials and methods : the patients were included in a prospective, controlled, randomized, not blinded study. They were patients requiring controlled mechanical ventilation with minute ventilation > 10 l/min for more than 3 days. They had to be sedated and paralyzed. Following a randomized order, the patients were ventilated for 24h periods with the Bennett Cascade 2 Humidifier and the Humid-Vent Filter. The Pall Ultipor filter was studied over a period of 45 min. In each patient, during the inspiration phase, the following measurements were performed : mean and minimum values of temperature, relative and absolute humidity of inspired gases.

Results and discussion : the Bennett Cascade 2 Humidifier and the Humid-Vent Filter had a better thermic capacity than the Pall Ultipor Filter (p < 0.001). With regard to relative humidity, no difference at any time was observed between the Bennett Cascade 2 Humidifier and the Humid-Vent Filter. The Pall Ultipor Filter achieved a lower performance when compared with the other two systems (p < 0.007). Concerning absolute humidity of inspired gases, the Pall Ultipor Filter achieved a lower performance than any other tested systems (p < 0.02). A small but significant decrease in temperature and absolute humidity, but not in relative humidity was seen after 24h of use with the Humid-Vent Filter. However, with this filter all patients had absolute humidity > 28 mg H_2O/l and relative humidity > 93% after 24 hours of use.

Conclusion : in patients with minute ventilation > 10 l/min, the Humid-Vent Filter has a thermic and humidification capability close to the reference system, the Bennett Cascade 2 Humidifier. The Pall Ultipor Filter has a significantly lower capability in these patients.

A.21

TOLERANCE OF PREOPERATIVE TRANSESOPHAGEAL ECHOCARDIOGRAPHY IN PATIENTS SHEDULED FOR AORTIC SURGERY

Marilyn Gosgnach, Françoise Le Bret, Nadia Smail,
Marc Beaussier, Pierre Viars
Department of Anesthesiology, CHU Pitié-Salpêtrière,
University Paris VI, Paris, France.

Background and goal of the study: Transthoracic echocardiography represents a non invasive approach to assess cardiac function before aortic surgery but is often inadequate because of the high rate of COPD in this population.By contrast Transesophageal echocardiography(TEE) provides high quality imaging of the heart.The aim of the study is to appreciate the tolerance of such a procedure in this high risk population.

Material and methods:31 consecutive patients scheduled for aortic surgery were included in this study.Hypertension was noted in 15 patients , clinical CAD in 12 and COPD in 11. The probe was inserted after topical anesthesia with lidocaine and midazolam sedation. Mean arterial pressure (MAP), heart rate (HR) and oxygen saturation(SaO_2) were noted before the procedure, during the probe insertion, during the examination at 2 minutes interval and 2 min after the probe removal .A computerized ST segment analysis was used to detect myocardial ischemia .

Results: The insertion of the probe provoked an increase in MAP lasting 4 minutes. Throughout the procedure the heart rate remains significantly increased. 5/31 patients developed episodes of silent myocardial ischemia, at the probe insertion (n=4) and during the procedure (n=1).They lasted less than 2 min in all but one patient in whom it persisted until the probe removal. No decrease in SaO_2 was noted .

	control	intro	intro+2	intro+4	removal	remov+2
HR(bpm)	76±14	100±20 *	91±21*	86±18*	89±20*	82±16*
MAP (mmHg)	96±16	110±20 *	105±18 *	104±18 *	93±14	89±13
SaO_2 (%)	96±2	96±2	96±2	96±2	96±2	96±2
ST< (n)	0	4	4	1	1	0

* $p<0.05$ vs control (x ± SD, ANOVA)

Conclusion: Although TEE is a very useful means to assess LV function before aortic surgery , it is associated with significant hemodynamic and ischemic ST segment changes. Control of the hemodynamic response to probe insertion seems desirable during this procedure in this patient population.

A.22

DIPYRIDAMOLE-TEE AND 24 h HOLTER-ECG AS PREOPERATIVE SCREENING TESTS FOR CORONARY ARTERY DISEASE IN PATIENTS WITH ABDOMINAL AORTIC ANEURYSM.

Margareta Östman, Mats Karling, Kjell Karp, Dag Teien and Sebastian Reiz

From the Departments of Anaesthesia and Clinical Physiology, University of Umeå, Umeå, Sweden.

Background and goal of study: Patients with aortic atherosclerotic disease have a high prevalence of covert coronary artery disease (CAD). Several adjunct tests, such as dipyridamole-thallium scintigraphy (DTS), have been proposed for risk assessment and identification of patients requiring coronary angiography. Recent studies have shown poor performance of the DTS technique in these respects (1,2). We present our *initial experience* of dipyridamole-transoesophageal echocardiography (dip-TEE) and 24 hour 2-lead Holter ST-segment recording in the detection of significant coronary artery stenosis in patients with abdominal aortic aneurysms.

Patients and methods: After institutional approval, 15 consecutive, elective aortic surgical patients were subjected to preoperative coronary angiography, dip-TEE and 24 h 2-lead Holter ECG (II + V5). Myocardial ischaemia by dip-TEE was defined as new systolic wall motion abnormalities (SWMA-s) developing during low (0.56 mg/kg) or high (0.80 mg/kg) iv dip infusion and by Holter ECG as a reversible ST-segment depression of 0.2 mV or more recorded in at least one lead. A significant coronary stenosis was defined as an obstruction of the diameter of at least one vessel by 50% or more. The indication for coronary intervention was based on the angiographic findings independently of the results of the two other tests.

Results and conclusions:

	n=	*Pos. dip-TEE*	*Pos. Holter*
no CAD	**4**	**2**	**1**
CAD			
<50%	**1**	**0**	**0**
>50%	**10**		
CABG/PTCA indic.	**5**	**4**	**5**
Not indicated	**5**	**0**	**0**

We conclude that the *positive and negative predictive power* of dip-TEE (pos./neg.: *67%/89%*) and Holter ECG (pos./neg.: *83%/100%*) in identifying aortic surgical patients with indications for CABG or PTCA, found in this pilot study, are sufficiently high to warrant further studies of these techniques in this patient population.

A.23

EVALUATION OF HAEMODYNAMIC INDICES OF MYOCARDIAL ISCHAEMIA IN PATIENTS WITH CORONARY ARTERY DISEASE (CAD)

Per Hohner, Göran Johansson, Sören Häggmark, Vipin Mehta, Sebastian Reiz

From the Department of Cardiothoracic Anaesthesia & Surgery, University of Umeå, Umeå, Sweden.

Background & goal of study: Haemodynamic indices such as rate pressure product (RPP=SAPxHR), pressure rate ratio (P/R=MAP/HR) and pulmonary arteriolar occluded pressure (MPAOP) are regarded as valuable adjuncts to ECG monitoring to indicate when the risk for myocardial ischaemia (MI) is increased (1,2). This study evaluates the sensitivity and specificity of RPP, P/R and MPAOP for MI provoked by atrial pacing and blood pressure (BP) manipulation in patients with CAD.

Patients & methods: Sixteen patients with proximal LAD stenosis were studied during general anaesthesia prior to coronary surgery. MI was induced by step-wise increase in HR by atrial pacing, while BP was kept constant. After recovery, and with HR kept at control level by pacing, blood pressure was increased (BP↑) or decreased (BP↓) in a random fashion to the same RPP and P/R as at end-point pacing by the use of phenylephrine and nitroprusside, respectively. MI was defined as a change of the spatial ST-segment vector magnitude (STC-VM) >50 uV and/or myocardial lactate production. Myocardial oxygen consumption (MVO2) was derived from coronary blood flow by thermodilution and arterio-coronary sinus oxygen content differences at each measurement. Values of haemodynamic indices tested for sensitivity and specificity were: RPP>12.000, P/R<1.0 and MPAOP>15 mm Hg.

Results & discussion: Eighty measurements were analyzed (16 controls, 16 pacing-induced MI, 16 at the pacing step prior to MI, 16 at BP↑ with 3/16 MI, and 16 at BP↓ with 3/16 MI). MVO2 was lower at the MI threshold than at BP↑ (10.1±7.2 vs 12.7±6.0 ml/min, $p=0.030$) but higher than awake (8.2±5.4 ml/min, $p=0.009$). MVO2 during BP ↓ (5.9±2.4 ml/min) was lower than awake ($p=0.044$). Sensitivity/specificity: RPP: 27%/83%, P/R: 77%/55%, MPAOP: 5%/95%. We conclude that P/R is a moderately useful haemodynamic index of MI during tachycardia with normal BP but not during hypotension with normal HR. A major reason for this discrepancy, observed despite a lower P/R during BP↓ (0.70±0.13 vs 0.86±0.08, $p<0.001$), is that MVO2 at BP↓ was only 60% of the value during pacing-induced MI. Although specific, neither RPP, nor MPAOP are sufficiently sensitive indices of MI.

A.24

THE USE OF THE CUSUM PLOT FOR DETERMINATION OF MYOCARDIAL ISCHAEMIA THRESHOLD DURING ATRIAL PACING IN PATIENTS WITH CORONARY ARTERY DISEASE.

Sebastian Reiz, Göran Johansson, Per Hohner, Sören Häggmark

From the Department of Cardiothoracic Anaesthesia and Surgery, University of Umeå, Umeå, Sweden.

Background and goal of study: Myocardial lactate extraction (MLE) data used to diagnose myocardial ischaemia clinically are difficult to interpret for several reasons; *First,* lactate is used as a substrate at the same time as it is released at the onset of ischaemia; *second,* blood sampled in the coronary sinus might not include outflow from the ischaemic territory, or might be diluted from non-ischaemia territories, *third,* flow through an ischaemic territory may be too low, or the ischaemic territory too small, to offset a clear decrease in MLE. The true incidence of ischaemia will hence be underestimated if myocardial lactate production (MLP) is used as an index of ischaemia (1). The goal of the study was to analyse if the CuSum plot, a graphical statistical technique (2) which enhances trend changes, could indicate the onset of lactate release, measured as MLE, during atrial pacing. Simultaneously, we performed the same test using a vectorcardiographic (VCG) ST-segment criterion for ischaemia.

Patients and methods: After institutional approval and informed consent, 15 patients with predominant LAD stenosis were studied during general anaesthesia prior to coronary surgery. They were subjected to incremental increase in heart rate by atrial pacing at constant blood pressure till arterio-great cardiac venous blood analysis demonstrated, MLP. A computerised VCG was analysed for changes in STC-VM (change of spatial ST-vector magnitude). In patients with CAD, a change of STC-VM >50 uV is indicative of ischaemia. Numerical values of MLE and STC-VM were entered in the CuSum plot in which the third of the five or six pacing step values was used as the reference point.

Results and conclusions: The start of lactate washout could be easily identified by the CuSum plot in all patients. It coincided with MLP in 2/15 only (MLE=10.4±10.0% vs 13.3±7.0% at control, means±SD, n.s.) and abnormal STC-VM (75±37 uV vs 9±4 at control, $p<0.01$) in 12/15. At the next pacing step, 8/15 had MLP (MLE 0.7±7.3%, $p<0.01$ vs control) and 15/15 had abnormal STC-VM (117±41 uV, $p<0.01$ vs control). At the last pacing step, MLE was -3.1±4.0% and STC-VM 131±45 uV. We conclude that the CuSum plot is sensitive for identification of ischaemic threshold during atrial pacing, using MLE as an index of ischaemia. VCG STC-VM is, however, significantly more accurate ($p<0.0001$ at the ischaemia threshold and $p=0.003$ at the next step) than MLE for this purpose.

EVALUATION IN INTENSIVE CARE OF THE FRACTION AREA CHANGE OBTAINED BY AUTOMATIC BORDER DETECTION.

N. Liu*, P. Catoire*, J. Rosso**, M. Saada#,
F. Bonnet.*
* Réa Chir ** Nuclear Med H. Mondor hospital, 94010
Créteil France, # DAR, Pitié Paris France.

The manual measurement of the fraction area changes (FAC) of the left ventricule obtained by trans-esophageal echocardiography (TEE) has been documented to be correlated with isotopic ejection fraction (EF)[1]. An echographic Automatic endocardial Border Detection algorithm (ABD) is now available, allowing to calculate on-line FAC [2]. The aim of this study was to compare the FAC obtained by ABD with isotopic EF

Methods : 10 mechanically ventiled critical ill patients were studied. Simultaneous, TEE and radionuclide images were obtained with Technetium 99m in each patient, before and after dobutamine(5 mcg/kg/min). The set was performed in radionuclide imaging unit. FAC were measured at the midpapillary muscle level. TEE used a 5-MHz oesophageal trans-ducer (Hewlett-Packard Sonos 1000 Andover®).

Results : The figure shows the correlation between FAC measured by ABD and EF measured by radionuclide (r=0,85). Bias (FAC-EF), precision, and agreement coefficient R with and without bias correction are summarized in the table.

	Bias	Precision	R	R Limits
FAC vs EF	-9,4	9,84	0,74	0,88-0,45
FAC vs EFcorr	-0,4	9,84	0,85	0,94-0,67

Discussion : A good agreement was obtained between FAC and isotopic EF. Agreement increased after Bias correction. We conclude that FAC obtained by ABD is accurate for the EF evaluation in ventilated patients.

A.26

SENSITIVITY AND SPECIFICITY OF MECHANICAL AND ELECTROCARDIOGRAPHIC MYOCARDIAL ISCHAEMIA (MI) MONITORING TECHNIQUES.

Per Hohner, Vipin Mehta, Michel Saada, Sõren Häggmark, Erica Jansson, Gõran Johansson, Sebastian Reiz

Department of Cardiothoracic Anaesthesia and Surgery, University of Umeå, Umeå, Sweden and Department of Anaesthesia, Pitié-Salpêtirère Hospital, Paris, France.

Background & goal of study: New systolic wall motion abnormalities (SWMA) by transesoephageal echocardiography (TEE) are generally considered as the most sensitive and specific indicator of myocardial ischaemia (MI) (1). Recent animal data have documented lack of specificity with increased loading conditions (2). The goal of this study was to determine the sensitivity and specificity of TEE, 12-lead ECG (ECG) and computerized vectorcardiography (VCG) for MI during atrial pacing and changing loading conditions, using myocardial lactate production (MLP) as the end-point for ischaemia.

Materials and methods: 14 patients with proximal LAD stenosis were studied during anaesthesia prior to coronary surgery. They were subjected to stepwise increase in heart rate by atrial pacing (AP) till MLP. After recovery, they were randomly subjected to elevation and reduction of blood pressure (BP↑/BP↓) by phenylephrine and sodium nitroprusside to rate pressure products and pressure-rate ratios identical to those obtained at end-point pacing respectively. A deterioration of regional LV function by at least 2 steps on a 5 degree scale, in at least 1/4 segments of the cross-sectional image at the mid-papillary level was considered as MI by TEE. The ECG criterion was a new horizontal or downsloping ST-segment depression >0.1 mV, 60 msec after the J-point. The VCG criterion was a change of the spatial ST-segment vector magnitude (STC-VM) >50 uV, 60 msec after the J-point.

Results & discussion: 16 episodes of MLP (AP:14, BP↑ :1, BP↓:1) were recorded during the 42 measurements. Sensitivity/specificity:ECG: 69%/100%, VCG: 88%/96%, TEE: 50%/92%. During AP, ECG, VCG and TEE were positive for MI before MLP occurred in 5/14, 11/14 and 4/14 respectively. TEE was positive for MI before ECG or VCG in 2/14. We conclude: (1) TEE is less sensitive and not more specific than ECG/VCG techniques in detecting MI by MLP, (2) MLP is a late indicator of MI. Possible reasons for lack of TEE sensitivity: (a) the ischaemic area was not sampled at the midpapillary level (b) interpretation of new SWMA-s during tachycardia is difficult.

PULMONARY AND SYSTEMIC VASCULAR EFFECTS OF ISOPROTERENOL, NITROGLYCERIN AND PROSTAGLANDIN E1 EARLY AFTER CARDIAC OPERATIONS IN PATIENTS WITH PULMONARY HYPERTENSION

J Alvarez, ML Camara, J Cortiñas, J Cortes, A Aris

Department of Anaesthesiology, Hospital Xeral De Galicia, Santiago De Compostela & Cardiac Surgery Unit, Hospital De La Santa Creu I Sant Pau, Barcelona, Spain

Background and goal of study: Patients with mitral stenosis and some degree of right ventricular failure may benefit from inotropic or pulmonary vasodilator drugs in the early postoperative period.

Materials and methods: 40 patients undergoing surgery for mitral stenosis were randomized to four groups: "C" (n=10) no drugs, "I" (n=10) isoproterenol 5 ng/kg/min, "N" (n=10) nitroglycerin 0.5 ug/kg/min and "P" (n=10) prostaglandin E1 0.08 ug/kg/min. After 18 h, the vasoactive drugs were reduced to 1/2 of the initial dose and 3 h later they were discontinued. Measurements of haemodynamics including cardiac index (CI), systemic vascular resistance (SVR) and pulmonary vascular resistance (PAR) were made after surgery without drugs (D0), and 1h (D1), 12h (D2), 18h (D3), 21h (D4) and 24h (D5) after institution of the respective drug.

Results: * denotes p<0.05 compared with group "C".

A.28

ECHOCARDIOGRAPHIC STUDY OF THE INDUCTION WITH A LOW-DOSE OF SUFENTANIL FOR CORONARY ARTERY SURGERY

N. Bromberg, C. Decoene, E. Chammas, A. Pol,
R. Krivosic-Horber

D.A.R.C. 1, Hopital B, CHRU de LILLE,
59037 LILLE CEDEX. FRANCE.

BACKGROUND AND GOAL OF STUDY : Sufentanil has the advantage of shorter recovery time and less postoperatively respiratory depression than fentanyl when it is used for coronary artery bypass grafting (CABG) surgery (1). Because increasing the dose of sufentanil does not produce a dose related suppression of hemodynamic and hormonal responses to surgical stimulation, some investigators have suggested that smaller doses of sufentanil should be used (2). This study was designed to evaluate the hemodynamic responses of a low dose of sufentanil throughout the induction.

MATERIALS AND METHODS : Ten patients scheduled for an elective CABG surgery whose resting left ventricular ejection fraction (EF) was greater than 50% were studied. Preanesthetic medication consisted of scopolamine and midazolam. Prior to induction, 500 ml of Haemaccel^{r} was infused. Anesthesia was induced with pancuronium (0,1mg/kg) and **sufentanil 5mcg/kg in 5 minutes.** Cardiac output (CO) and EF were monitored by trans-thoracic echocardiography. Hemodynamic measurements (Mean Arterial Pressure, Heart Rate, CO, EF) were taken just before induction (T1), at the end of sufentanil infusion (T2), after intubation (T3), and 20 minutes after infusion of sufentanil and before surgery (T4). Anesthesia was maintained with 50% nitrous oxide and an infusion of 0,1mcg/kg/min of sufentanil continued until just prior to the institution of cardiopulmonary bypass, with a bolus (50 or 100mcg) of sufentanil before the sternotomy, with additional bolus of sufentanil (50mcg) given whenever MAP reached >20% above preanesthetic values. The total amount of sufentanil administered was 21,8 +/- 2,1 mcg/kg. Postoperatively, the patients were transferred to Surgical Intensive Care Unit (SICU) where segment ST changes were assessed and mechanical ventilation was performed until awakening. Statistical analysis used the Wilcoxon matched-pairs signed ranks test ; p<0,05 was accepted as significant.

RESULTS AND DISCUSSION : The hemodynamic measurements taken throughout the induction are reported in the table1. HR and CO increased slightly after intubation. This hemodynamic stability corresponds to the stability reported by Thomson using 15mcg/kg of sufentanil (1) and by Philbin using 10, 20, or 30mcg/kg of sufentanil (2). The patients were ready for extubation 877 +/- 257 min after their arrival in SICU.

CONCLUSION : In conclusion, a low dose of sufentanil can be administered with adequate hemodynamic effects and without the need of any other hypnotic and allows an earlier awakening and extubation.

GASTRIC MUCOSAL PERFUSION IS BETTER PRESERVED DURING CARDIAC SURGERY WHEN ISOFLURANE RATHER THAN ENFLURANE OR PROPOFOL IS USED TO MAINTAIN ANAESTHESIA.

Monty Mythen, Deborah Browne, Colin Hamilton-Davies, Andrew Webb. The Bloomsbury Department of Intensive Care and The Department of Anaesthesia, The Middlesex Hospital, London, UK

Background and goal of study: We have previously shown that peri-operative gastric mucosal hypoperfusion is associated with a poor outcome following elective major surgery [1]. The aim of this study was to compare the effects of propfol, isoflurane and enflurane on gut mucosal perfusion in patients undergoing elective coronary artery bypass graft surgery (CABG).

Materials and methods: 30 patients with good pre-operative ventricular function undergoing elective CABG. Routine measurements of heart rate (HR), blood pressure (BP) and right atrial pressure (RAP) were made. In addition cardiac output (CO) and stroke volume (SV) were determined by oesophageal Doppler measurement of aortic blood flow and gastric mucosal perfusion by tonometric assessment of gastric mucosal pH (pHi). Patients were randomised following admission to the trial to receive either Enflurane (group E [n=10]), Isoflurane (group I [n=10]) or Propofol (group P [n=10]) for maintenance of anaesthesia. Otherwise patients were managed according to a standard anaesthetic protocol.

Results: There were no significant differences in demographic details or baseline values for mean HR, BP, CO, SV, RAP or pHi between the three study groups. In all 3 groups BP was unchanged from baseline to end of surgery. Group I patients maintained their mean pHi from baseline to end of surgery and demonstrated a significant rise in CO ($p < 0.05$) and SV ($p < 0.05$). Group E and P patients had significant reductions in mean pHi from baseline to end of surgery ($p < 0.01$). In group E patients there was a significant increase in CO ($p < 0.05$), HR ($p < 0.001$) and RAP (0.05) but no change in SV. In group P patients there was a significant increase in HR ($p < 0.01$) but no change in CO, SV or RAP.

Conclusion: Patients are more likely to maintain gastric mucosal perfusion during elective CABG if anaesthesia is maintained with Isoflurane rather than Enflurane or Propofol as part of a balanced anaesthetic technique.

PROPOFOL/FENTANYL-ANESTHESIA IN PATIENTS WITH HIGHLY DEPRESSED CARDIAC FUNCTION

Helmut Rauch, Franz Fleischer, Rainer Haußmann, Bernd Böttiger, Eike Martin

Dpt. of Anaesthesiology, University of Heidelberg, Germany

Background and aim of study: Our aim was to study whether hypotensive phases during Propofol/Fentanyl anesthesia in patients with reduced cardiac function could be avoided by pre-induction volume loading or whether catecholamines are still required.

Materials and methods: Before anesthesia was induced, 13 patients (ASA III-IV with highly depressed cardiac function), who were undergoing implantation of an automatic defibrillator, were catheterized under local anesthesia with a 20 G cannula (left radial artery) and a rapid response thermistor Swan Ganz^{R} catheter (right internal jugular vein). 10 ml/kg of Ringer's solution was infused and anesthesia was induced with 15mg/min Propofol (Disoprivan^{R}, ICI Pharma) and 0,1 - 0,2 mg Fentanyl^{R} (Janssen). At preset time intervalls (T1: pre induction, T2: shortly before intubation, T3:immediately after intubation, T4: 5 min. after intubation, T5: steady state, T6: before skin incision, T7: 5 min. after skin incision, T8: at the end of defibrillations) heart rate (HR), mean arterial pressure (MAP), mean pulmonary arterial pressure (MPAP), PAWP, CVP, cardiac index (CI) and right ventricular ejection fraction (RVEF)were measured. From these data right ventricular enddiastolic volume index (EDVI) and systemic vascular resistance (SVR) were calculated. CI and RVEF were measured using a computer (Explorer^{R}, Baxter Ltd.)

Results and discussion: There was an evident decrease of MAP after induction and during maintenance of anesthesia. At the same time MPAP increased. PAWP increased in only one case. CI decreased continously, whereas SVR decreased for only a short period after induction. The right ventricular parameters were stable at all times.

These results are similar to those found by Haessler et al (1992) in a comparible group of patients.

Conclusion: Decrease of MAP and CI in critically ill patients under Propofol/Fentanyl anesthesia cannot be avoided even by sufficient pre infusion of volume. Therefore use of catecholamines and installation of invasive monitoring seemes to be justified.

A.31

ACCURACY OF PROCESSED AUDITORY EVOKED RESPONSE IN PREDICTING MOVEMENT DURING CARDIAC SURGERY

H. Kuppe, K.-F. Klotz, S. Eleftheriadis, H. Gehring, W. Gerling
Department of Anesthesiology, Medical University of Luebeck, Germany

INTRODUCTION: Processed EEG has been used to assess anesthetic adequacy. The auditory evoked response has been shown to correlate with the levels of anesthetic agents. No study has examined the correlation of processed auditory evoked potential (AER) variables in response to surgical procedures. The purpose of this study was to determine whether processed variables such as the spectral edge frequency (SEF) and mean frequency (MF) provides additional information about anesthetic depth in patients undergoing cardiac surgery.

METHODS: After Human Investigation Committee approval and informed consent auditory evoked potential monitoring was performed in 30 patients undergoing cardiac surgery. After premedication with flunitrazepam anesthesia was induced with fentanyl. After tracheal intubation with pancuronium the lungs were ventilated with air-O2 without inhalational agents. Additional fentanyl (0.5 µg*kg^{-1})and flunitrazepam (0.5 mg) was given before skin incision, sternotomy, and aortic-atrial cannulation. AERs were recorded using a Nicolet Pathfinder. Impulse: binaural click (70 dB); rate: 9.7 Hz; derivation: Cz (pos), A1/A2 (neg); filter: 5-1000 Hz. In order to achieve a result from 2.5 Hz for each spectral analysis the timebase was lenghtened and stimulated fourfold, whereby 4 AERs were registered. Recordings were obtained continously from the waking state.

RESULTS: The following phases were investigated: T1 (awake), T2 (after induction), T3 (hypothermia), T4 (after extracorporal circulation), T5 (during intraoperative movement). The characteristic peak latencies (V, Pa, Nb) and the AER variables like SEF and MF are shown in the **table**: Latency values (*=p<0,01).

table	T1	T2	T3	T4	T5
V (msec)	6.1±0.1	7.0±0.1•	9.1±0.2•	7.1±0.1	6.9±0.3
Pa(msec)	29.4±0.4	34 3±0.5•	41 2±0.9•	32.9±0.4•	31.0±1.3
Nb(msec)	43.8±1.5	54.9±1.2•	64.3±1.1•	52.4±0.8•	47.8±2.7
SEF (Hz)	49.0±1.7	36.3±1.2•	28.1±1.7•	39.6±1.4•	43.6±2.5
MF (Hz)	22 0±1 3	16.8±0.4•	13.3±0 5•	17.3±0.7•	18.6±1.1

DISCUSSION: Latency measurements obtained from AEP recording present a possibility to predict intraoperative movement, which was observed in four patients. Assessment of processed AEP variables such as SEF and MF appears to enhance further diagnostic accuracy as this data supports the concept of a relationship between AEP and anesthetic depth. Advanced signal processing methods can provide guidelines to the administration of anesthesia in order to prevent intraoperative arousal.

A.32

CEREBRAL BLOOD FLOW VELOCITIES (CBFV) DURING ANAESTHESIA FOR GYNAECOLOGICAL LAPAROSCOPIC SURGERY.

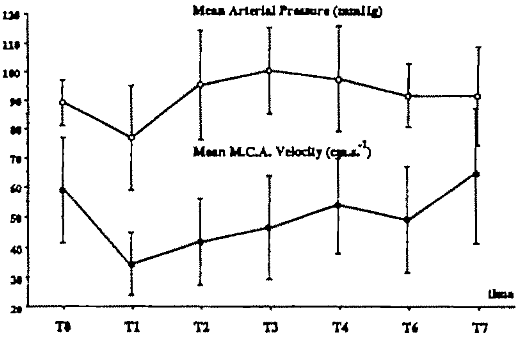
Jean Claude Granry, Christine Monrigal,
Jean Paul Jacob, Jean Pierre Monrigal

Department of Anaesthesia and Intensive care
University of Angers, Angers, France

Goal of Study : The increase of the abdominal pressure and the pneumoperitoneum during laparoscopic surgery (and anaesthesia for these procedures) induce hemodynamic and respiratory changes. We investigated these consequences on cerebral circulation using transcranial doppler sonography (TCD).

Materials and methods : 11 fully informed patients (age : 33,8 ± 8,4 yrs. weight : 54,9 ± 10,1 kg) scheduled to undergo pelvic laparoscopic surgery were enrolled in this study. The same anaesthesia was given to all patients, induced with midazolam, propofol, fentanyl and atracurium, and maintained with nitrous oxide (50 %) in oxygen and propofol (5 mg.kg^{-1} h^{-1}). Aftor intubation, ventilation was adjusted to keep PetCO$_2$ between 30-35 mm Hg. HR, NIBP, SpO$_2$ and PetCO$_2$ were monitored continuously . TCD (EME TC 2-64 device) measurements (systolic Vs, mean Vm, diastolic Vd velocities and resistance index RI) were obtained from the middle cerebral artery (MCA) before induction (T0), after induction (T1), after peritoneal insufflation with CO$_2$ (T2), after trendelenbourg position (T3), after exsufflation (T4) and after extubation (T7). Statistical analysis was performed with Kruskal-Wallis test.

Results and discussion : Following induction of anaesthesia and institution of hyperventilation, MAP and Vm decreased in all patients. At any time studied, the values were less but not significantly different than baseline (fig).



Conclusion : the results of this study indicate that there is no significant effect of laparoscopic procedures in these conditions on cerebral blood flow velocities of MCA studied by TCD.

A.33

NEUROENDOCRINE CHANGES DURING PNEUMOPERITONEUM FOR LAPAROSCOPIC CHOLECYSTECTOMY.

J. Joris, M. Lamy

Department of Anaesthesia, CHU Liège,
B - 4000 Liège (Belgium).

Background and goal of study: Haemodynamic changes induced by pneumoperitoneum result from mechanical factors, but probably also from humoral factors (1,2). This study investigated neuroendocrine changes during laparo-scopy, which might contribute to these haemodynamic changes and more particularly to the increase in systemic vascular resistance (SVR).

Materials and methods: 10 (9F-1M; aged 45±5) ASA I patients without cardiac pathology or medications scheduled for elective laparoscopic cholecystectomy were included in the study. General anaesthesia was induced with sufentanil 15-20 µg, thiopental 5 mg/kg and atracurium 0.5 mg/kg and maintained with $N2O:O2$ (50%) and isoflurane as needed. Ventilation was adjusted to keep end-tidal PCO_2 between 30-40 mmHg. Arterial blood samples were collected before induction (T1), 10 min after the induction, 10 min after tilting in the 10° head-up position (T3), 5 min (T4), 15 min (T5) and 30 min (T6), after the beginning of intraabdominal insufflation (14 mmHg) and 30 min after exsufflation (T7).Cortisol (CORT), renin, vasopressin (VASO), endothelin (ENDO) were measured using a RIA, and adrenaline (ADR) and noradrenaline (NA) using a HPLC. Data were analyzed by ANOVA followed by Newman Keul's test.

Results: Induction of pneumoperitoneum rapidly resulted in a massive release of VASO. VASO then decreased but remained above 20 pg/ml, the lowest plasma concentration for VASO to produce vasoactive effect. The profile of VASO release parralleled the time couse of SVR previously reported (1). Plasma concentrations of renin catecholamines also increased during pneumoperitoneum, but, these changes did not correlated with changes in SVR. Plasma concentration of ADR remained stable during pneumoperitoneum, and then further increased during recovery from anaesthesia. Increase in plasma concentrations of NA and renin rather reflected the stress response to surgery since they have similar time-course as CORT. Finally, ENDO did not change significantly during pneumoperitoneum.

	T1	T2	T3	T4	T5	T6	T7
VASO:pg/ml	3	7	2	175*	146*	43	22
ADR:ng/l	56	36	39	181*	196*	172*	556*
NA:ng/l	224	222	281	408*	486	470	489*
RENIN:pg/ml	11	13	25*	35*	51*	61*	38*
CORT: µg/l	67	53	82	107	175*	258*	287*
END:fmol/ml	26	24	25	23	20	30	30

*=$p<0.05$ as compared with T1

Conclusions: Several humoral factors might contribute to the haemodynamic changes during pneumoperitoneum. VASO, however, appears as a good candidate to explain the increase in SVR.

A.34

INFLUENCE OF PNEUMOPERITONEUM AND POSTURE ON HEMODYNAMIC AND STRESS RESPONSES DURING ANAESTHESIA FOR LAPAROSCOPIC SURGERY

Suzanne Odeberg, Olle Ljungqvist, Per Gannedahl,
Torgny Svenberg, Alf Sollevi.

Departments of Anaesthesia and Intensive Care, Huddinge University Hospital and Karolinska Hospital, Stockholm.

Background and goal of study: The use of pneumoperitoneum (PP), i.e. gas insufflation into the abdominal cavity, is increasingly used to improve surgical conditions. The physiological influence of PP is however not fully examined in humans. The present study investigates the influence of PP, and its combination with different body positions, on hemodynamics and on stress response.

Materials and methods: Patients without cardio-pulmonary disease (n=11, age 18-57 yrs) were studied by Swan-Ganz and radial arterial catheterisation, before and during laparoscopic cholecystectomy, under propofol-fentanyl anaesthesia with controlled ventilation. Mean arterial pressure (MAP), myocardial filling pressures (PCWP and RAP, measured with transducers at the level of the right atrium), and cardiac output (CO, transformed to CI) were determined in the horisontal position, with a 15-20° head-down tilt, and with a 15-20° head-up tilt. The measurements were repeated after insufflation of carbon dioxide to an abdominal pressure of 12-13 mm Hg. During surgery (duration range 1-2,5 h), measurements were performed at 30 minute intervals. Blood samples for analysis of arterial plasma catecholamines and cortisol were collected before anaesthesia, repeatedly during surgery, and postoperatively.

Results: The filling pressures were strictly dependent on body position. Alterations in body position, with or without PP, did not influence CI. PP during the horisontal position increased PCWP and RAP by approximately 40% ($p<0,01$) and MAP by approximately 30% ($p<0,01$). When PP was combined with a head-down tilt, there was a further increase in filling pressures by approximately 40% ($p<0,01$), while the reduction in filling pressures during the head-up tilt was counteracted by PP. During PP with a head-up tilt, the filling pressures were not different from the horisontal position without PP. The levels of catecholamines and cortisol were low throughout the investigation.

Conclusions: Alteration in body position as well as PP causes marked changes in myocardial filling pressures. The combination of PP and a head-up tilt is associated with normal filling pressures and stable myocardial function during surgery. It is suggested that prolonged PP, especially when combined with a head-down tilt, may be hazardous in subjects with compromised myocardial function. Laparoscopic cholecystectomy is associated with a low stress response as reflected by catecholamines and cortisol.

A.35

EFFECTS OF PLASMA VOLUME SUBSTITUTION ON RIGHT VENTRICLE VOLUMES AND FUNCTION USING ELOHES® AND PLASMION®.

JY Lepage, F Garrec, JM Malinovsky, A Cozian,
and M Pinaud.
Department of Anaesthesiology, Hôtel-Dieu, 44035
Nantes, France.

Background and goal of study: The choice of which fluid to give a patient for plasma substitution during major surgery remains controversial. Hydroxyethylstarch seems to be interesting in terms of volume expansion. duration of action, side effects and cost as compared with others colloid substitutes. The role of right ventricle during hypovolaemia and acute volume loading is important to consider. Thus we investigated right ventricular volumes and function following calibrated fluid resuscitation with Elohes® (E) and Plasmion® (P) in hypovolaemic surgical patients.

Materials and methods: After institutional approval and informed consent, 20 ASA III patients recovering from major urologic surgery were randomly and equally assigned to two groups to receive 500 ml of either E or P on a ante brachial vein for 15 minutes using an infusion pump. Monitoring was obtained from EKG, Swan Ganz equipped with a fast response thermistor and radial artery cannula. Inclusion criteria consisted of fluid deficit of 500 to 1000 ml, and a 20% decrease from preoperative values in central venous pressure, pulmonary wedge pressure and end-diastolic volume, in patients fully awake with removed endotracheal tube and normal body temperature. Seven series of measurements were made before (baseline), during (5,10,15 min) and after (30 min, 1 and 3 hours) volume expansion. At the same times, blood samples were withdrawn for plasma ANF determination. After transformation in % change from baseline statistics were carried out using ANOVA with repeated measures.

Results: The main results are summarised in the table.

		baseline	15 min	3 hours
HR	P	88±7	86±5	90±6
(b. min-1)	E	91±6	90±4	89±5
MAP	P	85±5	88±5	88±5
(mmHg)	E	78±5	83±5	83±4
PCWP	P	5±1	12±1‡	6±1†
(mmHg)	E	3±1	12±2‡	7±1†
SI	P	50±3	65±4‡	53±3‡
(ml. m-2)	E	38±3§	52±5‡	46±5‡
EDVI	P	107±7	139±8‡	110±8‡*
(ml. m-2)	E	78±10§	114±15‡	100±13‡*§
EF	P	50±2	48±2	50±2
(%)	E	52±3	49±2	49±2
O^2 systemic	P	16.7±2.1	16.2±2.2	14.8±1.3†
transport	E	10.0±1.4	14.6±3.4	14.5±3.3†§
ANF	P	55±16	78±22	85±24†
(pg. ml-1)	E	54±10	102±36	99±20†

mean ± SE; † $p< 0.05$; ‡ $p< 0.01$ vs. baseline; * $p<0.01$ vs. 15 min; § $p< 0.05$ E vs. P

Discussion and conclusion: During volume expansion indicators of preload increased similarly in the two groups. Three hours after volume expansion, end-diastolic volume and systemic oxygen transport remained higher in E group than in P group, suggesting a longer duration of action of volaemic expansion.

A.36

ALTERNATING RIGHT TO LEFT VENTRICULAR EJECTION; THE CASE OF OCCULT CARDIAC TAMPONADE.

Charissios Skourtis, Lazaros Karalazos, Demetrios Setzis.

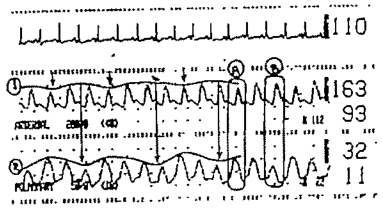
Department of Cardiac Anaesthesia and I.C.U, A H.E.P.A. G.H., Thessaloniki, Greece

Introduction: Early detection of cardiac tamponade (CT) may be of paramount importance to patients requiring any mode of positive - pressure ventilatory augmentation. Since the classic manifestations of CT may not be present at this stage and pulsus paradoxus occurs in other pathologic conditions as well, we undertook this study in order to examine the possibility of early detection of CT by comparing the waveforms of systemic and pulmonary artery pressures (SAP, PAP).

Methods: One hundred and twenty patients scheduled for cardiac surgery were included in the study, fullfilling the following criteria: SAP greater than 140 mmHg, CXray not indicative of CT, RAP within normal range, EF>45% and no sign of COPD. Complete haemodynamic profile was obtained by means of a Swan-Ganz catheter and an arterial line before administering any anaesthetic agent. A 3-channel recording of ECG, SAP and PAP was obtained and analyzed in each case by conventional planimetry and a computerized scanning - planimetry system, comparing corresponding beats of SAP and PAP. Since the area under a single pressure curve for a given beat is proportional to the stroke volume (SV) - the other factors remaining unchanged - , right and left SVs were compared in terms of relative values

Results - Discussion: Pulsus paradoxus of the PAP being out of phase to the corresponding puslus paradoxus of SAP was found in 4 patients (curves 1 and 2 in the tracing); this has been described by other investigators as a typical sign of CT.[1] Planimetric analysis showed the corresponding beats of SAP and PAP were inversely related in terms of SV values (e.g. A, B in the presented tracing). This can be explained by the presence of pericardial fluid inhibiting the smultaneous even fililing of the two ventricals (RV, LV) during a given moment of the respiratory cycle, systemic venous return to the RV being enhanced during inspiration, leaving diminished available pericardial space for the LV to dilate; the opposite occuring during expiration. The diagnosis was surgically confirmed (amounts of pericardial fluid: 250ml to 600ml) in all four cases.

Conclusion: We believe that analysis of the corresponding beats, as it is describedabove - even as a simple review of a recording (see tracing) - , of SAP and PAP waveforms may reveal the existence of occult CT before its classic manifestations supervene. The clinical implications of our method, applied in a general ICU population, remain to be seen.



---

DETERMINANTS OF SYSTOLIC PRESSURE VARIATION IN PATIENTS VENTILATED AFTER VASCULAR SURGERY

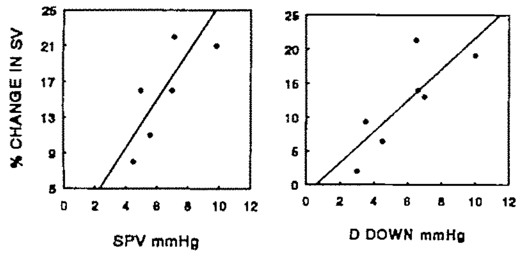
M. Beaussier, P. Coriat, M. Gosgnach, M. Portilla,
P. Kalfon, P. Viars
Department of Anesthesiology, CHU Pitié-Salpêtrière
University Paris VI, Paris, France

Perel et al. used systolic pressure variation (SPV) in response to positive pressure inspiration (PPI) as an estimate of stroke volume (SV) (1). These authors stated that an increased in SPV reflects a decrease in SV associated with hypovolemia. However, Denault et al (2) suggested that the decrease in SPV during PPI reflects withdrawal of the intrathoracic pressure effects on the arterial pressure. To determine the predominant determinant of SPV, we recorded simultaneously blood pressure (BP) and SV derived from beat to beat transoesophageal continuous wave Doppler trace.

Methods. We studied 7 patients who were sedated under mechanical ventilation following vascular surgery. Radial arterial pressure, airway pressure were simultaneously recorded. We measured SV at the following times : at the time of maximal and minimal systolic pressure (SP) during four mechanical breaths (difference in SP = SPV) ; during apnea and at the time of minimal SP during one cycle of mechanical breath (difference in SP = delta down).

Results. There exists a significant relationship between the decrease in SV and the magnitude of both SPV (r = 0.82) and delta down (D down) (r = 0.80).

	SPV	Delta down
Value in mmHg	7 ± 2	5.9 ± 2
% change in SV	17 ± 7	12 ± 7



Conclusion. The decrease in SP provoked by PPI reflects simultaneous decrease in SV. This suggests that a decrease in LV filling which limits ejection, rather than a fall in afterload, is responsible for PPI induced SPV. This finding confirms the interest of considering SPV to detect hypovolemia.

A.38

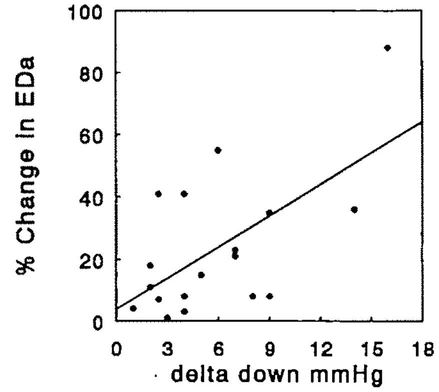
THE SYSTOLIC PRESSURE VARIATION PREDICTS RESPONSE TO VOLUME LOADING IN PATIENTS VENTILATED AFTER AORTIC SURGERY.

Pierre Coriat, Carlos Gomez, Georges Daas,
Azriel Perel, Pierre Viars.
Department of Anaesthesiology, CHU Pitié-Salpêtrière, Paris, France.

Background: As suggested by experimental (1) and clinical studies (2), the degree by which the systolic pressure (SP) decreases following a fixed tidal volume, termed delta down (ddown) is a sensitive indicator of hypovolemia. The aim of this study was to assess the ability of this parameter to predict LV function response to volume loading.

Patients and methods: We studied 18 patients who were sedated under mechanical ventilation following abdominal aortic surgery. Patients with LV ejection fraction < 35 %, PAOP > 18 mmHg or betablocker therapy were excluded from the study. The difference between the minimal SP during one cycle of mechanical breath and SP during apnea (ddown), TEE derived end diastolic area, and cardiac index were measured before and after volume loading with 500 ml of human albumin 4 %.

Results: The preinfusion ddown values showed a significant linear correlation to the increase in EDa (r=0.63) fig. and cardiac index (r=0.55) in response to volume loading. The higher the initial ddown the greater was the change in EDa and CI.



Conclusion: These findings indicate that in mechanically ventilated patients after vascular surgery, ddown is a useful means of cardiovascular assessment which provides reliable information concerning the LV response to volume loading.

A.39

INFLUENCE OF CHRONIC ANGIOTENSIN CONVERTING ENZYME INHIBITION ON SYSTOLIC PRESSURE VARIATION DURING ANESTHETIC INDUCTION

Louis Puybasset, Bart Oris, Pierre Coriat,
Marilyn Gosgnach, Pierre Viars.
Department of Anaesthesiology, CHU Pitié-Salpêtrière, Paris, France.

Background: By contrast to calcium channel blockers (CaB) Angiotensin converting enzyme inhibitors (ACEI) increase the lowering blood pressure effect of anesthetic induction (1). To better determine the mechanisms involved in this hypotensive response to induction we quantified systolic pressure variations (SPV) after induction of anesthesia in hypertensive (H.T.) patients chronically treated with ACEI. When SP decreased, SPV has be shown to be increased in case of low stroke volume associated with hypovolemia.

Methods: Blood pressure was recorded at induction in H.T. patients chronically treated with A.C.E.I. (n=15 group ACEI) or CaB (n=12 group CaB) and in 16 non treated non H.T. patients (group C). A standardized anesthetic technique was used in all these patients who underwent a vascular surgical procedure.

The S.P.V. and its delta down (ddown) component (difference between the value of minimal SP during one cycle of mechanical breath and SP during apnea) were determined after induction under mechanical ventilation when mean arterial pressure (MAP) was 20-30 % lower than the preoperative SP value. If MAP became lower than 30 % than its preoperative value phenylephrine was given.

Results: Are expressed as mean + SEM :

mmHg	C	CB.	ACEI
Preop MAP	95±2	100±4	93±2
SPV	6±0,6	6±0,8	8,5±0,7*
ddown	4±0,7	3,6±0,8	6,1±0,7*

ANOVA : * $p<0.005$ vs C and CB

Phenylephrine was needed in more pts in group ACEI (n=10) than in groups CaB(n=4) andC(n=2)p <0.05

Conclusion: The higher SPV due to by a mechanical breath in ACEI patients suggests that a decrease in the filling of the left ventricle which limits left ventricular ejection may contribute to the exaggerated hypotensive response to induction seen in this group.

A.40

KETAMINE DOES NOT PREVENT HYPOTENSION CAUSED BY INDUCTION OF ANAESTHESIA WITH PROPOFOL IN ELDERLY PATIENTS

Dirk Blockmans, Jan Van Hemelrijck, Hugo Van Aken
Department of Anaesthesia
Katholieke Universiteit Leuven, Belgium

Background and goal of study:

The combination of propofol with a subanaesthetic dose of ketamine has been recommended, when haemodynamically stable anaesthesia is required[1,2]. However, this recommendation may not be valid for every patient. The goal of this study was to investigate if administration of ketamine could improve the haemodynamic stability during induction of anaesthesia with propofol in elderly, vascular patients.

Materials and methods:

Thirty consenting vascular surgery patients, older than 60 years of age, were randomy assigned to 1 of 3 treatment groups. Baseline blood pressure (BP) and heart rate (HR) were recorded before the administration of fentanyl, 2 µg/kg, and ketamine, 0 mg/kg (Group 1), 0.5 mg/kg (Group 2) or 1 mg/kg (Group 3), respectively. Three min later anaesthesia was induced with propofol, 1.5 mg/kg i.v. over 30 sec, and vecuronium, 0.1 mg/kg i.v.. Three min later the patients were intubated and ventilated with 100 % O_2. BP and HR were recorded before and during 10 min after the administration of propofol. A decrease in SAP below 80 mmHg before laryngoscopy or by more than 20 % compared to baseline after intubation, was treated with ephedrine or neosynephrine. The need for vasopressor treatment was compared. Results are expressed as mean values ± S.D. Anova was used to compare the age. HR and BP for all measurement times and the maximal decrease in BP in the 3 Groups were compared using Kruskal-Wallis statistic; $p<0.05$ was considered significant.

Results and discussion:

The age of the patients was 70 ± 10 y (Group 1), 68 ± 5 y (Group 2), and 70 ± 6 (Group 3) (n.s.). BP and HR profiles during the observation period were identical in all Groups. Vasopressor treatment was necessary in respectively 5/10 (Group 1), 4/10 (Group 2), and 7/10 (Group 3) patients. Mean arterial pressure decreased by 47 ± 11 % (Group 1), 35 ± 26 % (Group 2), and 46 ± 10 % (Group 3) (p = 0.284).

Conclusion:

In elderly, vascular patients, the administration of a subanaesthetic dose of ketamine before induction of anaesthesia with propofol does not prevent hypotension.

EFFECTS OF NITROUS OXIDE (N_2O) ON SYSTEMIC HAEMODYNAMICS, REGIONAL LEFT VENTRICULAR (LV) FUNCTION AND INCIDENCE OF MYOCARDIAL ISCHAEMIA (MI) IN VASCULAR SURGICAL PATIENTS WITH CORONARY ARTERY DISEASE (CAD)

Per Hohner, Christer Backman, George Diamond, Arnold Friedman, Sören Häggmark, Göran Johansson, Kjell Karp, Sebastian Reiz

Departments of Anaesthesia and Clinical Physiology, University of Umeå, Umeå, Sweden and Departments of Anaesthesia and Cardiology, Cedars Sinai Medical Centre, Los Angeles, Ca, USA.

Background & goal of study: N_2O has been shown to produce systolic wall motion abnormalities (SWMA) in dogs when added to opiates or isoflurane (1,2). It is clinical experience that N_2O may produce cardiac depression in patients with CAD. However, new SWMA-s caused by N_2O, indicating myocardial ischaemia (MI), have not been observed in such patients (3). This study examines the effects of N_2O on systemic haemodynamics, anterior LV function and incidence of MI in vascular surgical patients with CAD.

Materials & methods: 47 patients with CAD were randomly assigned to isoflurane-fentanyl anaesthesia with N_2O/O_2 vs air/O_2 (control). Systemic haemodynamics, 12-lead ECG and anterior LV wall motion by cardiokymography (CKG) were recorded at four intervals: before and during anaesthesia, then 10 and 30 minutes into surgery. Haemodynamics were controlled by changing anaesthetic dose, and, when insufficient, by iv nitroglycerine (NG) in case of LV failure (PCWP>18 mm Hg), or by iv phenylephrine (PE) in case of arterial hypotension.

Results & discussion: *(1)* More pre-induction MI was observed in the control group ($p=0.043$). *(2)* More N_2O patients ($p=0.031$) needed NG to control PCWP during surgery despite comparable anaesthetic dose, blood pressure and heart rate. *(3)* MI, defined as myocardial lactate production, new ST-segment depression >0.1mV in at least one lead, and/or new SWMA on CKG without elevated LV loading conditions, was more frequent in N_2O patients ($p=0.029$). *(4)* Postoperatively, MI by serial ECG was noted in more control patients ($p=0.038$) most likely because these patients had more severe CAD (more pre-induction MI). The incidence of postoperative myocardial infarction was comparable. We conclude that N_2O, which is known to have both sympathomimetic and cardiodepressive actions, produced overt cardiodepression in the face of sympathetic stimulation during surgery. Our study design does not allow us to conclude if MI was the consequence of increased wall stress or a contributor to the LV dysfunction. Postoperative MI was not a consequence of intraoperative events but did rather identify patients at higher risk for MI.

A.42

EPIDURAL CLONIDINE AND MYOCARDIAL ISCHAEMIA AFTER ABDOMINAL AORTIC SURGERY

JP Fulgencio*, JM Rimaniol*, M Saada, P Catoire*,
F Bonnet***

**Departments of Anaesthesia, Hospitals H Mondor*,
94000 Créteil and Pitié Salpêtrière**, 75013 Paris, France**

Introduction: Clonidine (C) improves perioperative hemodynamic stability in high risk patients (1). C decreases arterial blood pressure and heart rate and may prevent the occurrence of myocardial ischemia (MI) but controversial data have been reported (2,3). We therefore conducted a blinded prospective study to assess if postoperative epidural C reduced MI in patients at risk.

Material and Methods: Forty five ASA 3 patients scheduled for abdominal aortic surgery were included in the study after informed consent and ethical committee approval. Surgery was performed under combined general and thoracic epidural anaesthesia. Postoperatively patients were randomly assigned to receive, in the recovery room, analgesia with a continuous epidural infusion of either fentanyl (0,4 mcg/kg/h) alone (F group) or fentanyl (0,4 mcg/kg/h) + C (0,3 mcg/kg/h) (F+C group). Patients were monitored during the first 24 postoperative hours with a ST segment analyser (Merlin^{R}, Hewlett-Packard), and pulmonary and radial artery catheters. MI was defined as a ST-segment decrease or increase over 1 mm from the base ligne, during at least 1 min. Hypotension was defined as a systolic arterial pressure < 90mmHg, hypertension as a systolic arterial pressure > 160mmHg and tachycardia as an increase in heart rate > 110bts/min. Hemodynamics events or MI were treated according to the judgment of the physician in charge of the patient, unaware of the analgesic regimen. Statistical analysis used Mann Withney U test and Fisher exact test. P<.O5 was considered significant.

Results: The 2 groups were comparable for demographics. 11 patients suffered of MI in the F group versus 6 in the F+C group (NS). The mean duration of MI was respectively 87±31min and 23±25min in groups F and F+C (NS). 21 and 11 episodes of MI occurred respectively in groups F and F+C in abscence of hemodynamic event while 16 episodes in both groups were associated with hemodynamic disturbances.

table 1: MI episodes according to hemodynamic events.

	hypotension	hypertension	tachycardia
F group	1	9	2
F+C group	0	1	3

($p<.05$)

Discussion: C may eventually blunt hypertension resulting from sympathetic activation from shivering or nociceptive stimulations in the recovery room and allows to avoid myocardial ischemia associated with increased oxygen demand, but the majority of MI events occurred without significant hemodynamic change. C may also be an appropriate treament of MI related to hypertension and tachycardia.

INFLUENCE OF POSITIVE PRESSURE VENTILATION ON MYOCARDIAL ISCHAEMIA AFTER ABDOMINAL AORTIC ANEURYSM REPAIR

D McCoy, M O'Connor, A Cunningham, R Dwyer

Department of Anaesthesia, Beaumont Hospital, Dublin 9, Ireland

Introduction: Ischaemic heart disease is common in patients presenting for abdominal aortic aneurysm repair and myocardial ischaemia is a major cause of postoperative morbidity and mortality[1,2]. Ventilatory support postoperatively might be useful by allowing heavy sedation and ensuring adequate oxygenation. We will present data comparing the incidence of postoperative myocardial ischaemia between patients who received postoperative positive pressure ventilation and patients who breathed spontaneously within 15 min of the end of abdominal aortic aneurysm resection. Preliminary data are described in this abstract.

Methods: Continuous ECG monitoring was instituted preoperatively to detect ischaemia in leads II and CM5 in 11 patients undergoing elective aortic aneurysm repair. After benzodiazepine premedication, anaesthesia was induced by thiopentone and fentanyl 2-5μg/kg and muscle relaxation provided by vecuronium. Anaesthesia was maintained by isoflurane in N_2O in O_2 and vecuronium administered as required. An epidural catheter was inserted before induction of anaesthesia; after release of the aortic cross clamp patients received an epidural infusion of bupivacaine 0.25% Four patients received positive pressure ventilation (mean duration 7 h) (Group I) and 7 patients were allowed to breathe spontaneously after antagonism of neuromuscular blockade and once adequate ventilatory function had returned (Group 2). The number and duration of episodes of significant S-T elevation or depression were compared between the two groups (Mann Whitney).

Results: Pre-operative Goldman scores and perioperative BP and HR were similar in both groups. There were no episodes of S-T depression in Group 1. In Group 2 the median number (quartiles) of episodes of S-T depression was 3 (0.75-3.75) ($p<0.05$) and of total duration of S-T depression was 3.9 (0.9-9.8) min ($p<0.05$).

Conclusion: Preliminary data suggest postoperative ventilatory support may decrease postoperative myocardial ischaemia after abdominal aortic aneurysm resection..

FUNCTIONAL RECOVERY AFTER 24h PRESERVATION OF RABBIT HEARTS IN UNIVERSITY WISCONSIN SOLUTION

JL Fellahi, F Ouardali, S Mouren, J-F Baron, M Diaby, P Viars

Department of Anaesthesiology, Hôpital Pitié-Salpêtrière, Paris, France

Introduction. Complete myocardial functional recovery after 24 hours storage in the University Wisconsin Solution (UWS) has been demonstrated. However, two different groups of hearts with and without ischemia were used in these studies. Our approach was to compare the myocardial performance of isolated blood-perfused rabbit hearts before and after 24 h hypothermic preservation in UWS.

Method. Reconstituted blood with red blood cells and modified Krebs-Henseleit buffer was oxygenated and equilibrated to achieve normal acid-base balance. After aortic canulation, the coronary network was perfused at constant perfusion pressure of 80mmHg using the langendorff technique. The speed of the coronary pump reflects the coronary blood flow (CBF). An atrial pacing maintained a constant heart rate of 120 b/min. A cannulated fluid-filled balloon was inserted in the left ventricule(LV) to maintain constant LV volume and to monitor the LV pressures. Maximal positive and negative LV pressure derivatives were derived and reflected respectively myocardial contractility (dP/dt max) and relaxation (dP/dt min). Baseline measurements were obtained one hour after aortic canulation (Control). Cardiac arrest was obtained by infusion of cooled UWS and the heart was stored in 4°C UWS. After 24 hours preservation, reperfusion was performed for 2 hours. Five additionnal hearts stored for one hour were used as control group to determine the effects of our protocol on functional recovery. Arterial and venous samples were withdrawn before the cardiac arrest and at 60,90,and 120 minutes reperfusion. The statistical significance was determined by ANOVA.

Results. Ten hearts were used for the statistical analysis. Hemoglobin value did not vary during the study. When compared to control, CBF was lower at 60 minutes reperfusion and unchanged at 90 and 120 min reperfusion. Decreased dP/dt max and dP/dt min were observed during the reperfusion period. The significant decrease in myocardial oxygen consumption (MvO2) during reperfusion was associated with a lactate production. A 10% impairment of dP/dt max was observed in the 5 control hearts.

Discussion. In this study, 56% functional recovery is observed after 24 h storage in UWS. This impairment in myocardial performance is related to an imbalance between oxygen supply and demand as demonstrated by the decrease in MvO2 and the lactate production.

EFFECTS OF HYPERTONIC SALINE ON CORONARY BLOOD FLOW AND MYOCARDIAL PERFORMANCE OF A BLOOD-PERFUSED, ISOLATED RABBIT HEART

S Delayance, G Mion, S Mouren, J-F Baron, M Diaby, P Viars

Department of Anaesthesiology, Hôpital Pitié-Salpêtrière, Paris, France

Introduction. Hypertonic saline is proposed for treatment of hemorragic shock. Its effects on volemia and peripheral vessels are demonstrated whereas its myocardial effects remain debated. Indeed, the observed increase in myocardial performance could be mediated through direct or indirect mecanisms. In order to determine the effect of hypertonic saline on the coronary blood flow and myocardial performance, increasing sodium concentrations ([Na]) were infused to isolated blood-perfused rabbit hearts. The studied concentrations included the [Na] observed in vivo after hypertonic saline infusion.

Method. Reconstituted blood with red blood cells and modified Krebs-Henseleit buffer was oxygenated and equilibrated to achieve normal acid-base balance. After aortic canulation, the coronary network was perfused at constant perfusion pressure of 80mmHg using the langendorff technique. The speed of the coronary pump reflects the coronary blood flow (CBF). An atrial pacing maintained a constant heart rate of 100 b/min A cannulated fluid-filled balloon was inserted in the left ventricule(LV) to maintain constant LV volume and to monitor the LV pressures. Maximal positive and negative LV pressure derivatives were derived and reflected respectively myocardial contractility (dP/dt max) and relaxation (dP/dt min). Blood perfusates with increasing [Na] from Na 140mM/l (Control) to 180 mM/l were infused. Between each infusion, the control perfusate was infused and time was allowed to return to baseline values. Arterial and venous samples were withdrawn for blood gas analysis before and after each hypertonic infusion. Statistical significance was determined by ANOVA.

Results. CBF increase significantly with [Na] higher than 140 mM/l. dP/dt max and dP/dt min increased with all the studied [Na]. dP/dt max reached its peak value for Na 160mM/l. The myocardial oxygen consumption (MvO2) increased with all the studied [Na].

Conclusions. In this study, a coronary vasodilation is demonstrated in the range of [Na] observed in vivo after hypertonic saline. This effect is related both to the perfusate osmolarity and the increase in MvO2. The increase in myocardial contractility and relaxation reflect the direct effects of the hypertonic saline on the myocardial fibers.

A.46

PRE- AND INTRAOPERATIVE PREVENTION BY β-BLOCKERS, PROPRANOLOL AND ESMOLOL, OF ISCHAEMIA-INDUCED VENTRICULAR FIBRILLATION

M Freysz, Q Timour, L Bertrix, J Loufoua, G Faucon

Med Pharmacol Dept, Cl Bernard University, Lyon, France

It is common to use ß-blockers in subjects with angina pectoris or even acute myocardial infarction to improve tolerance to ischemia by reducing mechanical energy expenditure of the heart, especially in the case of an underlying excess of sympathetic activity. The balance between cardiac energetic metabolism and coronary blood flow is maintained below the threshold triggering serious disorders including ventricular fibrillation, the most dramatic of these disorders in patients with coronary disease. The goal of this study was to better define the benefit which might be obtained from ß-blockers using a pig model.

The study was conducted in domestic pigs premedicated with i.m. droperidol and anesthetized with i.v. flunitrazepam and chloralose, whose core temperature was kept constant. After left thoracotomy, the left anterior descending coronary artery was dissected a few millimeters below its origin and a snare passed around it to produce complete occlusion. Occlusion was maintained until the onset of fibrillation in order to measure time to fibrillation (TF), which is altered by factors or drugs which change the vulnerability to fibrillation for a given rate. Additionally, two monophasic action potentials (MAPs) were continuously recorded, one in the area transiently subjected to ischemia and one in a non-ischemic area.

In group 1 ($n = 20$), the TF measurement was perfomed during atrial pacing at a rate just above the sinus rate. As ß-blockers are chiefly used to counteract excessive adrenergic influence, the animals received an i.v. infusion of isoproterenol 0.25 μg/kg/min and, in addition, 15 min after the start of isoproterenol infusion, propranolol 0.05 mg/kg ($n = 8$) or esmolol 1.00 mg/kg ($n = 6$). In group 2 ($n = 12$), propranolol ($n = 8$) or esmolol ($n = 4$) were administered in the absence of isoproterenol, but under pacing at a constant high rate, 180 bpm.

In group 1, TF was considerably reduced by isoproterenol (263 ± 59 to 69 ± 30 s), then came back to its control values 5 and 20 min (235 ± 85 s) ($P < 0.05$) after the injection of propranolol. The restoration of TF was less complete with esmolol (184 ± 68 s) ($P < 0.05$) at 5 min and not as long lasting, since the difference with control values ceased being significant at 20 min. This time course of TF was related to sinus rate, slowed down by propranolol (161 ± 17 to 103 ± 11 bpm) ($P < 0.05$), as well as by esmolol (156 ± 15 to 112 ± 16 bpm) ($P < 0.05$). Bradycardia also was responsible for the widening of MAP by 30 or 40 % with both drugs, in the ventricle not subjected to ischemia. However, during the ischemic periods, MAP duration underwent the same reduction as usual. In group 2, in the absence of any variation in heart rate (180 bpm) and MAP duration (220 ms), TF (near 100 s) did not appear to be significantly influenced by the administration fo propranolol or esmolol.

We conclude that propranolol or esmolol are capable of preventing ischemic ventricular fibrillation by controlling tachycardia of sympathetic origin. The effects of propranolol are longer and of interest preoperatively. The effects of esmolol do not exceed 5 to 10 min and are more suitable for avoiding an intraoperative tachycardia episode. However, the protective action does not result from a direct ventricular effect, but from the influence on heart rate, as the prolongation of TF is always associated with a fall in heart rate and dissappears under pacing at constant rate. In addition, variations in pacing rate similar to those in sinus rate due to isoproterenol and ß-blockers provide the same change in TF.

ENDOCARDIAL ENDOTHELIUM MODULATES IN VIVO LEFT VENTRICULAR PERFORMANCE

Stefan G. De Hert *, Thierry C. Gillebert, Dirk L. Brutsaert

Department of Anaesthesia (*), Department of Physiology
University of Antwerp, Antwerp, Belgium

Background: Selective damage of endocardial endothelium (EE) modulates myocardial performance in isolated cardiac muscle (1, 2) and in the intact ejecting ventricle (3). We analyzed the relevance of this phenomenon under different experimental conditions.

Methods: The dogs were instrumented with LV micromanometer, left atrial pressure, LV segment length gauges and right atrial pacing. EE function was transiently impaired with an ultrasound (UL) probe ($P = 25W$; $f = 0.9$ Mhz) in the LV cavity (3). The effects of UL were evaluated under different conditions of LV volume, contractile state and after mild selective alpha$_1$-adrenergic stimulation.

Results: In protocol A ($n = 10$), LV volume was altered with caval vein occlusion and intravenous dextran infusion. The UL probe was activated at low, mid and high LV end-diastolic pressure (EDP). Effects of UL were less pronounced at higher EDP ($p < 0.001$). In protocol B ($n = 7$), LV inotropic state was altered by slow intravenous infusion of low dose calcium. The UL probe was activated before and after calcium. Effects of UL were less pronounced after calcium ($p < 0.001$). In protocol C ($n = 7$), effects of UL were evaluated at baseline and after mild selective alpha$_1$-adrenergic stimulation (propranolol + phenylephrine (PE)). Effects of UL were similar at baseline and after propranolol but increased after PE.

Conclusion: UL modulated LV performance by transiently impairing EE function. These effects were more important at low volume and at lower calcium and under mild selective alpha$_1$-adrenergic stimulation.

DOES CAPTOPRIL MODIFY THE ARTERIAL RESPONSE TO VASOPRESSOR SUBSTANCES ?

Eric Le Pelley*, Thierry Chataigneau**, Jean-Pierre Richer***, Robert Tricoche**, Jacques Fusciardi*

(*)Departement of anesthesiology,(**)Laboratory of animal physiology, (***)GRTMV, University of Poitiers, Poitiers, France.

Background and goal of study: Captopril, an angiotensin-converting enzyme inhibitor, has a vasodilatory activity which depends on the renin-angiotensin system. It has also a direct endothelium-dependent vasodilatating action. During the induction of anesthesia in patients treated by Captopril, hypotension is often observed. The purpose of this study was to investigate the effect of Captopril on the vascular response to vasopressor substances in swine femoral artery rings.

Materiels and methods: Vascular rings (2,5mm in length and 2mm in diameter) were suspended in tissue baths and optimal tension determined. The integrity of the endothelium of each ring was assessed by the Acetylcholine (10^{-7}M)-induced reversion of a Kcl (20mM)-increased contraction. Then the rings were repeatedly washed, and the tension returned to the initial level. Renin (1mUI/ml) was added in all baths, and after 45 min. either captopril (100 microM) or water (control) were added. After 15 min., the rings were constricted with increasing doses(10^{-10} to 10^{-3} M) of Epinephrine, Norepinephrine, Phenylephrine, Ephedrine, Dopamine or Angiotensin II.

Results and discussion: The concentration-response curves for each vasopressor substances are the same with or without Captopril. As shown by the figure , ED_{50} are the same with or without Captopril.

Conclusion: Therefore Captopril(100 microM) doesn't modify the constrictive substances-induced vascular response of swine femoral arteries.

DOES EXOGENOUS DOPAMINE REVERSE CARDIOVASCULAR DEPRESSION INDUCED BY ISOFLURANE DURING THORACIC EPIDURAL BLOCKADE?

C. Raner MD, B. Biber MD, J. Lundberg MD,
J. Martner MD, Ola Winsö MD.

Dept. of Anesthesiology, University of Gothenburg,
Östra Hospital, Gothenburg, S-416 85 Sweden

Background and aim: Cardiovascular support by exogenous adrenergic receptor agonists is clinical routine to counter the depressor responses during epidural or spinal sympathetic blockade. Cardiovascular depression by inhalational agents is on the other hand usually managed by decreasing the dose of the anesthetic agent, which also causes alterations in anesthetic depth. This constitutes a significant risk for awareness. The aim of this study was to evaluate the cardiovascular effects of exogenous dopamine (DA) during isoflurane (ISO) anesthesia, as combined with a thoracic epidural blockade (TEA).

Materials and methods: DA (10 and 20 $\mu g \cdot kg^{-1} \cdot min^{-1}$) was infused in mechanically ventilated dogs during chloralose anesthesia before and during the combined administration of ISO (1.4% in 50 % O_2;1.0 MAC) and TEA (extension of sympathetic blockade including Th_4). Heart rate (HR), mean aortic pressure (MAP), mean pulmonary artery pressure (MPAP), pulmonary artery occlusion pressure (PAOP), cardiac output (CO; thermodilution), left ventricular end-diastolic pressure (LVEDP) and the maximum rate of change of left ventricular pressure (LV dP/dt) were measured.

Systemic vascular resistance (SVR) was calculated. Statistical significance was assessed by analysis of variance (ANOVA) and least square means.

Results and discussion:

Prior to ISO-TEA, DA increased MAP, CO and LV dP/dt. ISO-TEA decreased HR, MAP, CO and LV dP/dt, while SVR, MPAP and PAOP were not changed.

During ISO-TEA, the DA-induced increases in MAP and SVR were significantly more pronounced than prior to ISO-TEA. At the dose 10 $\mu g \, kg^{-1} min^{-1}$, DA restored MAP, CO, and LV dP/dt to levels found before ISO-TEA. At the DA dose 20 $\mu g \cdot kg^{-1} \cdot min^{-1}$, HR was restored to and MAP (39%), LVdP/dt (119%), SVR (28%) and MPAP (70%) were increased above levels prior to ISO-TEA.

Conclusion: Exogenous DA effectively and dose-dependently counters cardiovascular depression induced by the anesthetic technique of combining ISO and TEA. The pressor and systemic vasoconstrictor actions of DA are indicated to be potentiated by this combined anesthetic approach.

A.50

LOCAL VERSUS NEUROGENIC VASODILATOR EFFECTS OF DESFLURANE AND ISOFLURANE IN THE SMALL INTESTINE

H.Sundeman, B.Biber, O.Winsö, J.Martner,
C.Raner.

Dept. of Anesthesiology, University of Gothenburg,
Östra Hospital, S-416 85 Gothenburg, Sweden.

Background and aim: The general cardiovascular profile of action of the new volatile anesthetic desflurane (D) is similar to that of isoflurane (I), although data on regional hemodynamic effects of D are sparse (1). The aim was to evaluate vasodilator mechanisms of D and I in the intestinal vasculature.
Materials and methods: D or I was injected into a closed anesthesia circuit for cats (n=11) during basal chloralose anesthesia and controlled normoventilation. Hemodynamic measurements included heart rate (HR), mean arterial pressure (MAP) and small intestinal blood flow (IBF; optical drop flowmetry). Intestinal vascular resistance (IVR) was derived.
To avoid changes in local vascular tone related to transluminal pressure alterations, intestinal perfusion pressure (IPP) was controlled and kept constant by a variable aortic clamp. Measurements were made at 50 mmHg IPP during control and during the randomized subsequential administration of D (3.5% and 7.0%) and I (0.8% and 1.6%), i.e. doses corresponding to 0.5 MAC and 1.0 MAC respectively.
The registration sequence was repeated after intestinal postganglionic denervation.
Results: D and I dose-dependently decreased MAP. At each MAC level, this depressor response was more pronounced for D than for I. In the *innervated* intestine, D and I both dose-dependently decreased IVR. At the highest dose of each agent, D decreased IVR more than I. Denervation of the intestine significantly reduced base-line vascular resistance.
In the *denervated* intestine, a less pronounced vasodilation, as compared to the innervated state, was produced by both D and I. Both agents produced similar degrees of vasodilation. Also, the vascular relaxation was not dependent on the given dose of either agent.
Conclusion: D and I are both dilators of the intact intestinal vasculature, although 7,0% D seems more powerful than 1,6% I. In the denervated intestine, less powerful intestinal vasodilation was observed, suggesting that actions mediated through remote nervous vascular control mechanisms are significant for the vascular intestinal effects of both D and I. Denervation data indicate that, for the vasculature in the intestine, local control mechanisms have a different dose-response relationship than remote control mechanisms. This applies to both D and I.

A.51

A COMPARISON BETWEEN VARIOUS HEMODYNAMIC PARAMETERS REFLECTING PRELOAD DURING GRADED HEMORRHAGE IN VENTILATED DOGS.

Sergei Preisman, Alexander Shneider, Ulrich Pfeiffer,
Azriel Perel
Department of Anesthesiology, Sheba Medical Center,
[Sackler School of Medicine, Tel Aviv University]
Tel Hashomer, Israel 52621, and Pulsion Medizintechnik,
Munich, Germany.

Background and goal of study: The estimation of the volume status is a major part of monitoring critically Ill patients. Two new parameters for preload assessment have been recently introduced:1. The dDOWN, which is the difference between the minimal systolic blood pressure (SBP) during one mechanical breath and the SBP during a short apnea(1). 2. The intrathoracic blood volume (ITBV),which is measured by a double indicator (temperature and dye) dilution technique (2). We have compared the correlation of these two parameters to other hemodynamic parameters which are used conventionally for volume status assessment.
Materials and methods: Eight dogs were anesthetized, ventilated and bled by 10% ,20% and 30% of their blood volume. The dogs were then retransfused (RET) and loaded with 10 ml/kg of plasma expander (LOAD). Central venous (CVP) and wedge (WP) pressures were measured at each point, in addition to cardiac index (CI) and ITBV. The dDOWN was measured by a computer program and expressed in absolute values (mmHg), or as % of the SBP during apnea (% dDOWN).
Results and discussion: The results of the study are presented in the following table (mean ± SD):

	baseline	10%	20%	30%	RET	LOAD
dDOWN (mmHg)	7.0 ±4.3	9.3* ±3.1	11.2* ±3.1	11.9 ±2.9	7.8* ±2.3	4.7* ±2.7
%dDOWN (%)	5.6 ±3.2	8.1* ±2.9	9.8* ±3.2	11.1 ±3.8	5.4* ±1.9	3.0* ±1.8
ITBV (ml/kg)	29.7 ±4.5	26.8* ±5.3	23.9* ±4.3	23.1 ±3.0	30.8* ±4.7	35.2* ±4.9
CI (ml/kg/ min)	159 ±44	128* ±43	109* ±37	96* ±29	170* ±48	195* ±59
SVI (ml/kg)	1.3 ±.4	1.0* ±.3	0.8* ±.3	0.7* ±.2	1.2* ±.4	1.4* ±.4
CVP (mmHg)	5.5 ±.9	4.6 ±1.3	3.6 ±1.4	3.1 ±1.7	5.9* ±1.8	7.4 ±2.2
WP (mmHg)	8.0 ±.8	6.4* ±.9	5.4 ±1.4	5.1 ±1.2	9.1* ±2.2	9.9 ±2.7

* $p < .05$ in comparison to previous value

The following r values were found for correlation with the degree of volume change: dDOWN -0.64; %dDOWN -0.76; CI 0.63; SVI 0.63; ITBV 0.70; WP 0.72; CVP 0.67. There were signi-ficant correlations between ITBV and SVI (r=0.87), ITBV and dDOWN (r=-0.70), ITBV and %dDOWN (r=-0.77).
Conclusions: In the experimental setup of graded hemorrhage, the ITBV,dDOWN and %dDOWN reflect the volume status with the approximate same accuracy as commonly used hemodynamic parameters. This similarity may however change in other circumstances, such as heart failure. The dDOWN, being the least invasive of all variables measured in this study, is a clinically useful parameter for detecting changes in volume status.

A.52

INFLUENCE OF CERVICOTHORACIC EPIDURAL ANAESTHESIA (C-TEA) ON LEFT VENTRICULAR (LV) CONTRACTILITY - AN EXPERIMENTAL STUDY IN PIGS WITH AUTONOMOUS BLOCKADE.

Sebastian Reiz, Elisabet Nyström, Mehmet Tugrul, Sören Häggmark, Göran Johansson.

Department of Cardiothoracic Anaesthesia & Surgery, University of Umeå, Umeå, Sweden.

Background & goal of study: Electrophysiologic studies have shown that C-TEA produces effects on the heart similar and additive to those of beta-blockers (1). C-TEA has been shown to reduce infarct size in dogs (2) and alleviate unstable angina in humans (3). Dilation of stenotic coronary segments has been suggested as an important mechanism by which myocardial ischaemia is alleviated in patients (4). No experimental or clinical studies have, however, documented the effects of C-TEA on LV contractility, the most important contributor to myocardial oxygen requirements. The objective of this study was to investigate the influence of C-TEA on LV end-systolic pressure-volume relationships (ESPVR) and other indices of LV contractilitiy.

Materials & methods: Six female pigs were subjected to continuous pentobarbitone anaesthesia and autonomous blockade with hexamethonium and atropine. Atrial pasing was used to maintain heart rate constant. A conductance catheter was placed in the LV for derivation of LV volume (5) and pressure. Aortic and pulmonary arterial pressures, cardiac output and a V5 ECG were recorded. ESPVR was derived over 15 sec using inferior vena cava balloon occlusion. After baseline measurements, 5 ml 0.5% bupivacaine mixed with 2 ml dye were injected epidurally at the T2 level under fluoroscopy. Repeated ESPVR-s were obtained 15, 30 and 45 min after C-TEA.

Results & discussion: C-TEA (C3 to T6) did not decrease aortic pressure. The slope of ESPVR decreased from 2.3 ± 0.2 (mean±SD) at control to 1.6 ± 0.2 at 15 min, 1.4 ± 0.3 at 30 min and 1.5 ± 0.3 at 45 min (all $p<0.05$ compared to control). LV stroke work and LVdP/dTmax vs LV end-diastolic volume also decreased significantly. The results demonstrate that C-TEA decreased LV contractility by an average 39%. This is considerably more than could be expected from systemic haemodynamic measurements and could explain a major part of the beneficial effects of C-TEA on experimental and human myocardial ischaemia.

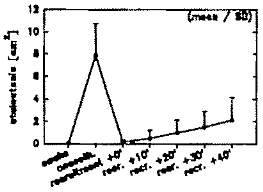
RECRUITMENT OF ATELECTASIS DURING GENERAL ANAESTHESIA: A CT-STUDY

Hans Ulrich Rothen, Bengt Sporre, Greta Engberg,
Göran Wegenius, Göran Hedenstierna
Institutes for Clinical Physiology / Anaesthesiology
and Intensive Care / Radiology,
Akademiska Sjukhuset, Uppsala, Sweden

Introduction: *Hypoxemia* during general anaesthesia is still a frequent finding [1]. The formation of *atelectasis* is one of the reasons for an altered gas exchange. Atelectasis is found in about 90% of all adult patients and there is a correlation between pulmonary shunt and atelectasis [2].

Question: Is it possible to reduce the amount of atelectasis by deep inflations of the lungs and do the recruited parts remain areated over time?

Material and Methods: Consecutive sample of lung healthy adults, scheduled for elective surgery. Intravenous anaesthesia (Propofol, Fentanyl, Pancuronium), controlled ventilation, end-tidal CO_2 4.0 kPa, FiO_2 4.0. Recruitment manoeuvre: Inflation of the lungs, three times up to an airway-pressure (P_{aw}) of 30 mbar and finally once up to P_{aw}=40 mbar. Every inflation was held for 15 seconds. Between these inflations, the lungs were ventilated conventionally for 2-3 minutes. Atelectasis was estimated as previously described [2]: For each analysis, a computed x-ray tomography was performed at end-expiration in a transverse plane 1 cm above the top of the right diaphragm. The atelectasis was calculated as amount of the dense areas (+100 to -100 Hounsfield units).



Atelectasis before and after Recruitment Manoeuvre

Results and Discussion: Up to now, 5 patients have been studied. Age (mean/range): 47/40-59 years, body weight (mean/range): 79/64-90 kg. Mean amount of atelectasis awake 0 cm², after induction of anaesthesia 7.9 cm². For changes after the recruitment manoeuvre, see figure. $P_{A-a}O2$ [kPa]: awake 1.4, anaesthesia 14.8; 5, 10, 20 and 40 minutes after recruitment manoeuvre: 10.7, 11.0, 11.9 and 11.9 respectively.

In previous studies, a reduction of atelectasis by PEEP has been found [3]. In contrast to our findings, there was however an immediate reappearance of the atelectasis after cessation of PEEP.

Conclusion: During general anaesthesia, atelectasis may be recruited by deep inflations of the lungs and the recruited lung-tissue remains areated in parts for at least 40 minutes. The mechanisms responsible for atelectasis formation and the prolonged effect of the recruitment manoeuvre remain to be elucidated.

THE RESPIRATORY COMPLIANCE IN NORMAL AND OBESE SUBJECTS DURING ANAESTHESIA

Davide Mulazzi, Emiliana Calappi, Massimo Croci

Servizio di Anestesia e Rianimazione, IRCCS Ospedale Maggiore, Milano, Italy

This study evaluates the effect of position change (supine vs prone) on the respiratory system compliance (Crs) in normal and obese patients during general anaesthesia.

Material and methods : We studied 18 normal and 6 obese (BMI ≥ 24) patients undergoing general inhalation anaesthesia for spinal cord surgery; all were mechanically ventilated (Servoventilator 900 C, Siemens). In supine position the airway pressure was recorded during an inspiratory hold (3 s) at TV 8 ml/Kg to compute TSLC; in 14 normal and 4 obese patients this manoeuvre was repeated at higher TVs to obtain the slope of the V-P curve (Cinf). After prone positioning (assuring free abdomen mouvements with upper chest and pelvic supports), we repeated all measurements.

Results and discussion : The results are reported in the table. In supine position TSLC was lower in obese than in normal patients ($p < 0.05$) while in prone position no difference was observed, due to both a TSLC reduction in normal patients and an increase in the obese ones. In all patients Cinf was higher than TSLC, suggesting an upward inflection point in the lower part of the V-P curve. No Cinf differences were observed between normal and obese patients both in prone and supine position.

Our result confirm that in anaesthetized obese patients fat and abdomen enchroaches on the respiratory system, shifting V-P curve below normal (1); in prone position this mass loading effect is lost, increasing TSLC to normal values for a subject receiving general anaesthesia in prone position.

	SUPINE	PRONE
TSLC (ml/cmH2O)		
Normal	49.9 ± 12.1	44.0 ± 10.8*
Obese	38.4 ± 6.5°	43.2 ± 6.4*
Cinf		
Normal	77.4 ± 12.2	66.5 ± 12.2*
Obese	65.9 ± 7.9	59.0 ± 3.1

° $p < 0.01$ supine vs prone
*$p < 0.05$ normal vs obese

CONTINUOUS SPIROMETRY: AN AID IN THE INTRAOPERATIVE RESPIRATORY MONITORING-CASE REPORTS

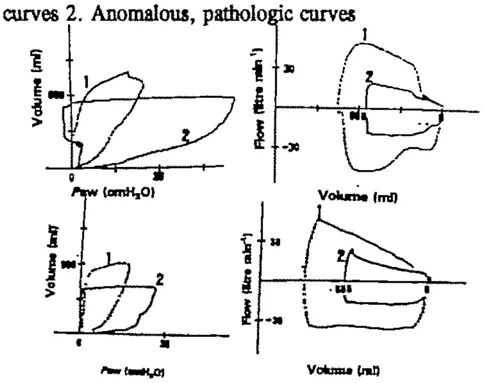
G.Bardoczky MD, E.Engelman MD.
A.d'Hollander MD,PhD.
Dept of Anesthesiology, Erasme University Hospital
808. Route de Lennik
1070 Brussels, Belgium

The Ultima SV™ respiratory monitor (Datex Instr. Helsinki, Finland) is used for routine intraoperative monitoring in our hospital. Spirometry is an integral part of the monitor equipped with a bi-directional flow sensor, which provides continuous measurements of inspiratory and expiratory flows, pressures and volumes(1). PV and FV loops are drawn from these parameters, displayed and updated continuously. Changes in compliance and airway resistance, or the expiratory flow characteristics of the whole respiratory system (lung, thorax, endotracheal tube) are depicted by the changing form of each loop. Compromised airway patency can alter the shape of the PV and FV curves in a particular way, which may be helpful to detect the origin of the problem.

We would like to present several cases, where the configuration of the curves was altered due to airway related complications.

Figure 1.

Pressure-volume (left panel) and flow-volume (right panel) curves recorded in a patient with kinked endotracheal tube (upper two curves) and in a patient with severe bronchoconstriction (lower two curves). 1.Baseline, normal curves 2. Anomalous, pathologic curves



COMMENTS

Both cases depicted here were associated with increased inspiratory pressures during mechanical ventilation. The right and downward shifted PV curve with enlarged area may illustrate this increased airway resistance. FV loops provide further information. The kinked endotracheal tube result both inspiratory and expiratory obstruction and equally diminished inspiratory and expiratory flow. Bronchoconstriction is characterized by diminished expiratory flow, and the convex configuration of the expiratory limb reveals uneven lung emptying.Continuous monitoring of PV and FV loops may be useful addition to detect compromised airway patency.

A.56

INFLUENCE OF POSTURE ON THE RESPIRATORY MECHANICS DURING ANESTHESIA

E.Engelman MD, G.Bardoczky MD.
A.d'Hollander MD.

Dept of Anesthesiology,Erasme University Hospital
808 Route de Lennik,1070 Brussels, Belgium

Changes in posture may influence the ventilation of the anesthetized, paralyzed subject(1). This study was carried out to observe the influence of the head-up and head-down positions on the ventilatory variables evaluated with a new flow sensor.

METHODS.Fourteen consenting,healthy women were anesthetized with continuous infusion of propofol.Their lungs were ventilated with a 100 ml/kg/min constant volume. A new, two-sided, pressure based flow sensor (2) measures flow, pressure at the endotracheal tube and integrates volume and other ventilatory data from these values. Pressure-volume and flow-volume curves are displayed continuously. Data were recorded after induction of anesthesia in the horizontal position; in the 25° head up, and in the 25° head down position. Data were compared with the Friedman's two way analysis of variance, $P < 0.05$ was significant.

RESULTS: In the head up position, no significant changes of the ventilatory parameters occured.The pressure-volume characteristics of the respiratory system did not change significantly (fig.1). Head down tilting of the patients resulted in significant increase in peak inspiratory (19.5±4 vs 16.9±4 cmH2O in horizontal), and plateau (15.2±4 vs 13±4 cmH2O in the horizontal) pressures, decrease in the compliance (49.4±11 vs 60.4±15 ml/ cmH2O).The pressure - volume curve shifted to the right, its slope was diminished. There was a heightening of the peak expiratory flow and an increased convexity of the terminal expiratory part of the flow-volume curve (fig.1).

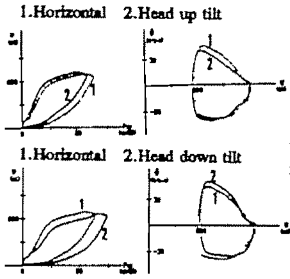

Figure 1.
Pressure-volume (left panel) flow-volume (right panel) curves

COMMENTS: When the diaphragm is paralyzed, its move is induced by the airway pressure, and opposed by the weight of the abdominal content. In the head up position, the visceral weight shifts away from the diaphragm- no ventilatory change will occur. In the head down position, the abdominal contents gravitate toward the diaphragm, the compliance of respiratory system decreased, and higher inflating pressure is required to achieve a given lung volume.This increased intrathoracic pressure may be poorly tolerated in a patient with cardiorespiratory compromise.

CONTINUOUS MONITORING OF THE VENTILATORY MECHANICS DURING ANAESTHESIA & INTENSIVE CARE

Carry Py*, Perdrix JP*, Baconnier P, Eberhard A**, Fargnoli JM**, Coppo F**, Banssillon V****

Department of Anaesthesia, Centre Hospitalier Lyon Sud* and PRETA, Fac. de Medecine, Grenoble, France**

Background and goal of study: Despite the high frequency of patients in the need of mechanical ventilation, few respiratory mechanical parameters can be monitored during anaesthesia and intensive care. We propose a system by which respiratory mechanics can be continuously monitored during these conditions.

Materials and methods: We continuously recorded tracheal pressure and flow (from the ventilator) in sedated patients subjected to controlled mechanical ventilation with constant flow insufflation and expiratory pause. A personal computer connected to the ventilator calculated 4 parameters: (1) **Rrs,Init**, e.g. the resistance of the respiratory system including the tracheal tube, (2) **Ers**, e.g. respiratory elastance, (3) **dPdiff/dT**, e.g. an estimate of the respiratory time constant inequality, and (4) **PEEPi**, e.g. the intrinsic positive end-expiratory pressure. These four parameters can be automatically calculated and stored over 24 h using a predetermined averaging period (expressed in min).

Results and discussion: After experimental adjustments of the four parameters, the system has functioned satisfactorily in patients during anaesthesia and intensive care conditions. These parameters can be obtained with a series of different ventilators, e.g. CFPO CESAR, PURITAN BENNETT 7200, SIEMENS-ELEMA 900C. Simultaneous recordings of tracheal pressure and flow signals by a Windograf Gould documented the accuracy of the measurements. The monitored PEEPi correlated well with PEEP measured during the end-expiratory paus.

Conclusions: We propose a system which reliably, non-invasively and automatically monitors respiratory mechanics during anaesthesia and intensive care.

A.58

CONTINUOUS MONITORING OF SpO2 DURING TOTAL INTRAVENOUS ANAESTHESIA WITH KETAMINE AND SPONTANEOUS VENTILATION

Luc-Marie Joly, Dan Benhamou

Département d'Anesthésie, Hôpital Antoine Béclère, Université Paris-Sud, 92141 Clamart, France

Background and goal of study: Total intravenous anaesthesia with ketamine (TIVAK) is widely used throughout the world especially in situations where oxygen is not easily available. When continuous monitoring of SpO2 was used in adult patients, few minor and transient desaturations were observed (1). However, several cases of respiratory distress have been reported and the safety of this technique has not been established in children.

Materials and methods: 76 adults and 64 children admitted at the Malte Order Hospital (Peshawar, Pakistan) from march to june 1992 and scheduled for peripheral surgery were randomised into two groups: Patients breathed either 40 % FiO2 (group 1) or room air (group 2) through a face mask from arrival in the operating room to complete recovery. Spontaneous ventilation was maintained throughout the study. Anaesthesia was started with 0.01 mg/kg of atropine, 0.1 mg/kg of diazepam and 2.5 mg/kg of ketamine. Then boluses of ketamine (1.25 mg/kg) were injected as required during surgery. SpO2 was continuously monitored using a pulse oxymeter and noted every five minutes. Respiratory events were recorded and a specific treatment was begun when SpO2 fell below 92 %. Statistics included two-way ANOVA for repeated measures and chi-square analysis as required.

Results and discussion: SpO2 decreased significantly 2 and 5 minutes after induction of TIVAK in adults breathing room air and 2 min after induction in children breathing room air. Respiratory events associated with desaturation occurred frequently in adults of group 2 (figure). One adult in each group required intubation immediately after induction (figure). In any patient was desaturation recorded later than 20 minutes after induction or during recovery.

Conclusion: Although SpO2 remained in the normal range during TIVAK and spontaneous ventilation in most patients, severe desaturations occurred, especially after induction in adults. Oxygen and equipment for intubation should be available.

HYPOXIC EVENTS AFTER GENERAL ANAESTHESIA IN THE RECOVERY ROOM

D Degasperi, M Vinelli, C Festa, MT Flandri

Department of Anaesthesia and Intensive Care, C Pizzardi Maggiore Hospital, Bologna, Italy

Background and goal of study: Several recent studies using pulse oximetry have identified preoperative risk factors associated with occurrence of hypoxaemic events after general anaesthesia, e.g. ASA physical status, surgical duration over 90 min, low preoperative SpO2 and history of smoking. We followed 85 patients after surgery and general anaesthesia to determine the incidence of hypoxaemia in the recovery room.

Materials and methods: Patients were monitored by pulse-oximetry with the probe placed on their index finger from arrival into the recovery room. SpO2 values were obtained 1, 5, 10, 15 and 30 min after arrival and hypoxaemia was arbitrarily defined as follows: 86-90% - mild, 81-85% - moderate, $\leq$ 80% - severe. If an SpO2 $<$ 90% was observed for more than 1 min patients received oxygen (FiO2 0.3 by Ventimask). If this proved insufficient FiO2 was increased by 0.1/min till SpO2 was above 90%.

Results and discussion: After 1 min we observed hypoxaemia in 23.5% of patients (age 55±14 y, ASA 1.4±0.7, SpO2 97±2, duration of surgery 166±101 min), after 30 min hypoxaemia was observed in 3.5%. After 5, 10, 15 and 30 min oxygen supplementation was given to 20%, 29%, 32% and 28% of patients respectively. The following risk factors for hypoxaemia in the recovery room were identified: duration and type of surgery (endocavitary), ASA physical status, preoperative SpO2 and presence of COPD. In general, over 30% of such patients were hypoxaemic during the first min, and 30 min later 40% needed oxygen supplementation. When comparing endocavitary surgery with superficial procedures we found the former to induce more hypoxaemia at 1 min (33% vs 12%, $p<0.05$), at 5 min (35% vs 13%, $p<0.05$) and the need for more oxygen supplementation at 10 min (41% vs 15%, $p<0.025$), at 15 min (46% vs 15%, $p<0.01$) and at 30 min (41% vs 13%, $p<0.01$).

Conclusion: We conclude that hypoxaemic events immediately after general anaesthesia are relatively frequent. Patients with risk factors have a higher incidence of hypoxaemia during the first postoperative min and have a greater need for supplementary oxygen which continues over the first 30 min.

A.60

INFLUENCE OF ANAESTHESIA ON POSTOPERATIVE HYPOXAEMIA

Loucas Georgiou, Anastasia Vourlioti, Fani Kremastinou, Pantelis Stefanou, Adelais Tsiotou
Department of Anaesthesia
Hippokration General Hospital, Athens, Greece

Anaesthesia provokes hypoxaemia postoperatively, but the contribution of volatile versus i.v. anaesthetics to hypoxaemia is not established. The **aim of the study** was to compair the incidence and degree of hypoxaemia perioperatively.

50 non-obese patients (pts), ASA I-II, aged 25-65, who were scheduled for elective cholecystectomy with Kocher's incision, of less thal 1,5 hour duration, were randomly divided into two groups. Group A (24 pts) received total i.v. anaesthesia (T.I.A.) with propofol (PRO), while group B (26 pts) received volatile anaesthetic [Isoflurane (ISO)]. On the night before surgery (NBS), arterial oxygen saturation (SaO_2) was continuously monitored with a Novametrix pulse oximeter from 22:00 A.M. to 6:00 P.M. All pts received the same preoperative sedation, and postoperative analgesia. Group A received PRO for induction, and continuous PRO infusion for maintenance. Oxygen enriched air was used in ventilation (FiO_2-33%). Group B received pentothal for induction and a mixture of 67% N_2O in oxygen supplemented with ISO (1-1,5%) for maintenance. All other anaesthetic agents were the same for the two groups. SaO_2 was continuously monitored for 8 hours after extubation (early postoperative period - E.P.P.) and during the first (N_1), second (N_2) and third (N_3) night after operation. Results were analysed using Wilcoxon's signed rank test and Mann-Whitney U. test. Values are median values (range).

Results

MEAN OXYGEN SATURATION					
	NBS	EPP	N_1	N_2	N_3
Group A	95,47 (94-97)	95,3* (93-97)	94,71 (92-97)	94,2 (88-97)	95,4 (91-97)
Group B	95,37 (93-96)	94,64 (92-97)	94,37 (90-96)	94,37 (91-96)	93,6 (90-97)
MINIMUM OXYGEN SATURATION					
Group A	92 (82-94)	91*** (77-96)	92** (85-94)	91 (84-94)	92 (82-94)
Group B	92 (89-96)	90 (78-93)	88 (79-94)	90 (83-94)	90 (81-94)

* $p=0.03$ vs group B, ** $p=0.01$ vs group B, *** $p=0.008$ vs group B

During E.P.P. Mean SaO_2 was higher in Group A compared to Group B. During E.P.P. and N_1 SaO_2 was higher in Group A compared to Group B.

In **conclusion** total i.v. anaesthesia with propofol is superior to Isoflurane-N_2O anaesthesia, in terms of lesser hypoxaemia. The lower incidence of hypoxaemia might be explained by differences in pharmacokinetic and pharmacodynamic effects.

A.61

EARLY POSTPERFUSION ASSESSMENT OF GAS EXCHANGE AND POSTOPERATIVE EXTUBATION OUTCOME FOLLOWING CORONARY ARTERY SURGERY

P. Knapik, J.B. Richardson, I. McLellan
Department of Cardiothoracic
Anaesthesia, Groby Road Hospital, Leicester, U.K.

Background and goal of the study: Patients for elective coronary artery bypass grafting (CABG) with good preoperative lung function are foreseen as candidates for early extubation. The goal of this retrospective study was to find out whether the first postoperative arterial oxygen tension (PO_2) may indicate the duration of required respiratory support.

Materials and methods: 100 patients with normal lung function who underwent uncomplicated CABG, were studied postoperatively. Anaesthetic technique was similar in all cases with high dose opioid technique excluded. Under these circumstances the decision regarding extubation was undertaken on the basis of conventional criteria for non-cardiac cases. First postperfusion PO_2 was correlated with the duration of postoperative ventilation in hours for each patient and was also compared to this time at different ranges of PO_2.

Results and discussion: Correlation of PO_2 with time of ventilation in hours resulted in significant correlation coefficient of -0.574. Comparing the mean time of ventilation to the PO_2 resulted in significant differences between ranges with a narrow standard deviation for the group with high postoperative p02 level (see table below).

PO_2 (kPa)	Mean Vent (Hours)	Number of Patients	Standard Deviation
10-20	11.1	21	+-3.4
20-30	7.7	38	+-3.1
30-70	5.3	41	+-1.9

Conclusion: We conclude that first postperfusion PO_2 may be recognised as a simple and reasonably reliable predicting factor for the period of post operative ventilation especially if it exceeds 30 kPa in patients after uncomplicated coronary artery surgery.

CEREBRAL PERFUSION DURING OBSTRUCTIVE SLEEP APNEA (OSA).

Eva Bålfors and Karl Franklin

Departments of Anaesthesia and Lung Medicine, University of Umeå, Umeå, Sweden.

Background & goal of study: A high incidence of cerebral and cardiovascular complications is found in OSA. Intemittent negative intrathoracic pressure, arterial oxygen desaturation and variations in blood pressure, stroke volume, heart rate and intracranial pressure (ICP) have been described. Our goal was to study the association between systemic hemodynamics and cerebral circulation during sleep apnea (SA). For this purpose, we followed cerebral blood flow velocity (CBFV) and wave form pulsatility (Pi) during SA.

Patients & methods: 12 patients with severe OSA were studied during sleep. Simultaneous recordings of CBFV, mean arterial pressure (MAP), transcutaneous CO2 and O2 tensions (PtcCO2, PtcO2), O2 saturation (satO2) and respiratory movements were performed at baseline during normal sleep, and during and after SA-s.

Results & discussion: 219 CBFV-s were recorded during 34 SA-s (range 10-60 sec) in 6/12 patients who developed SA-s. MAP and CBFV varied typically during and after SA. MAP and CBFV increased gradually to reach a peak 11±6% and 15±6%, respectively, above baseline ($p<0.001$) at the end of SA, and decreased to 8±2% and 11±6%, respectively, below baseline ($p<0.001$) after the first breaths. They were back to baseline within 60 sec. If repetetive SA-s occurred, MAP and CBFV did not recover from their low values until breathing was normal. PtcO2 and satO2 decreased significantly while tcPCO2 did not change during SA. CBFV and MAP correlated (r=0.67), suggesting slow cerebral autoregulation. Pi decrased by 9±6% ($p<0.001$) after SA suggesting cerebral vasodilation. Pi increased (34±15%, $p<0.001$) during the low CBFV after SA suggesting increased ICP. The described changes were not seen while patients were awake or during normal sleep. We conclude that OSA is associated with major variations in CBFV, Pi and satO2. Reduced cerebral perfusion, arterial desaturation and increased ICP may all contribute to the cerebral symptoms described in OSA.

RESPIRATORY EFFECTS OF LAPAROSCOPIC CHOLECYSTECTOMY (PRELIMINARY DATA)

MA Crea, L Sollazzi, V Perilli, E Marana, R Ranieri

Instituto di Anestesiologia e Rianimazione, Università Cattolica Sacro Cuore, Rome, Italy

Background and goal of study: Cholecystectomy by laparoscopic technique was first performed in 1987 (1) and can be applied to almost all patients with gallstones. Despite the rapid spread of this technique in the surgical community, there are few clincial anaesthesia studies. We report the respiratory and haemodynamic consequences of intraperitoneal carbon dioxide (CO2) insufflation for laparoscopy under general anaesthesia.

Materials and methods: 35 otherwise healthy patients suffering from symptomatic cholelithiasis were studied. After premedication, they were anaesthetized with isoflurane at 0.8 to 1.2% and mechanically ventilated. ECG, SBP, DPB, PAW, ETpCO2, ETiso, O2 saturation, arterial blood gases, intraabdominal pressure and insufflated CO2 volume (CO2vol) were recorded after induction of anaesthesia (T1), 5 min and 30 min after CO2 insufflation (T2 and T3) and 10 min after desufflation.

Results and discussion: There were no significant changes in haemodynamic parameters or paO2. paCO2 and ETpCO2 increased significantly at T2 and subsequently remained at these values (2,3). There were positive correlations between ETpCO2 and paCO2 at each measurement ($r=0.9$, $p<0.05$) and between paCO2 and CO2vol at T3 ($r=0.8$, $p<0.05$). Our data suggest minimal interference with gas exchange and mechanical ventilation. The amount of intraabdominally insufflated CO2 seems to induce an increase of paCO2 likely due to an absorption-diffusion phenomenon as indicated by the correlation between paCO2 and CO2vol.

Conclusion: Laparoscopic cholecystectomy is a safe technique in the healthy subject but should be safe also in patients with chronic obstructive lung disease and/or any other chest disease considering that laparotomy and major postoperative pain are avoided.

A.64

ABDOMINAL WALL RETRACTION MAY DECREASE ANAESTHESIOLOGICAL RISKS OF LAPAROSCOPIC CHOLECYSTECTOMY

Zsuzsanna Vereczkey, Barna Babik, János Fogas, Judit Méray, Béla Baltás.

Departments of Anaesthesiology and Surgery, Albert Szent-Györgyi Medical University, Szeged, Hungary.

Background and goal of study: The number of laparoscopic surgical and gynecological interventions has considerably increased in the last couple of years. The potential anesthesiological complications of these procedures have been extensively studied. Our aim was to reassess these problems in association with the use of a new surgical tool, the abdominal wall retractor (AWR).

Materials and methods: 20 patients were studied during laparoscopic cholecystectomy. 10 procedures were performed with conventional abdominal insufflation, and 10 with the use of AWR. Ataranaesthesia, intratracheal intubation and controlled mechanical ventillation were used. Parameters of the respiration were measured, the VCO2 vas registred by a mean stream capnograph (MSC), and percutanous pulsoxymetry (PPO) was also done. The cardiac output was detected by impedace cardiography, and the blood pressure was checked with a continuous non-invasive method.

Results and discussion : We found that an elevated pressure of CO2 in the peritoneal cavity caused considerable CO2 resorption with a concommittant increase in the VCO2 by 30 per cent. Decreased cardiac output was seen only in hypovolemic states, or at the time of PEEP ventillation. With the use of the AWR the intraabdominal pressure decreased from 12-15 mmHg to 5 mmHg ($p<0.05$). The volume of CO2 administred during the operation decreased considerably as well. The use of the AWR resulted in significant improvement in the parameters of mechanics of breathig. A decrease in the amount of absorbing CO2 was reflected in the significantly lower values of exhaled CO2 ($p<0.05$). The averege percutan O2 saturation was slightly higher in the AWR group (99% vs 97%, NS)

Conclusions: Based on our findings we hypothetise that the increased abdominal pressure results in increased airway pressures, dysteletasis of the basal pulmonal segments, and an increase in the intrapulmonary shunt circulation. The use of abdominal wall retractor may counteracts with this mechanisms. Abdominal CO2 absorption contributes significantly to the exhaled CO2 content. With the use of AWR this effect could be minimized.

A.65

DIAPHRAGMATIC FUNCTION AFTER BUPIVACAINE CERVICAL EXTRADURAL ANALGESIA FOR CHRONIC PAIN THERAPY

Elisabet Nyström, Erika Jansson, Britt-Inger Wenngren, Rajiv Sharma, Francois Clergue, Sebastian Reiz.

From the Departments of Anaesthesia and Otorhino-laryngology, University of Umeå, Umeå, Sweden and the Department of Anaesthesia, Tenon University Hospital, Paris, France

Background & goal of study: Extradural (ED) administration of steroids is a common therapy for cervical neurogenic pain and numbness due to osteoarthrosis. Most commonly, a local anaesthetic is used as carrier agent. The block consistently affects the nervous outflow to the diaphragm, which might potentially adversely affect respiratory function in patients with limited respiratory reserve. The aim of this study was to evaluate diaphragmatic function after cervical ED analgesia with bupivacaine used as carrier agent for depomedrone.

Patients & methods: 11 ambulatory patients with chronic pain due to osteoarthrosis were studied. They all had an ED catheter inserted to the C5 level via the C7/T1 interspace through which 3 ml at 5 mg/ml of bupivacaine mixed with 1 ml (40 mg) of depomedrone was injected after baseline measurements. These consisted of gastric (Pga) and oesophageal pressures (Poes), transdiaphragmatic pressure (Pdi), the relative contribution of rib cage and abdomen to quiet tidal breathing, and arterial blood gases. In addition, we assessed occulomotor function by EMG. All measurements were repeated 30 min after ED.

Results & discussion: The mean±SD spread of ED was from C3±0.6 to T6±1.2. Heart rate decreased from 75±12 to 69±9 bpm (p=0.013) as a sign of cardiac sympathetic blockade. Neither arterial blood gas tensions, nor Pdi were affected by ED. Respiratory rate and tidal volume remained unchanged (506±152 ml at control versus 441±180 ml after ED, p=0.068). The relative contribution of abdomen/rib cage to quiet tidal breathing remained constant at 73%/27%. Plots of $-\Delta Pga/\Delta Poes$ were not altered. Occulomotor function was signficantly impaired (p<0.0001). We conclude that cervical ED with a low dose bupivacaine (around 1.4 mg/segment) from C3 to T6 does not produce any evidence of diaphragmatic dysfunction or alteration of the contribution of rib cage and abdominal muscles to quiet breathing. It does, however, impair brain stem function as evidenced from decreased occulomotor function. This implies that adjacent respiratory nuclei could also be affected. The lack of alteration of respiratory function in our study could be explained by: 1. respiratory nuclei are more resistant to bupivacaine than occulomotor nuclei, 2. our techniques to explore respiratory function were less sensitive than the occulomotor test. Further studies with doses of bupivacaine used for surgical anaesthesia are needed to confirm the respiratory safety of cervical ED analgesia observed in the present study.

A.66

DIRECT, INDIRECT OR FLEXIBLE LARYNGOSCOPY AFTER THYROIDECTOMY ?

Louis Lacoste, Jérome Karayan, M. Suzanne Lehuedé, Pierre Ingrand, Jacques Fusciardi

Departments of Anesthesiology, Biostatistics and Surgery, Jean Bernard Hospital and University School of Medicine, 86021 Poitiers, France

Background and goal of study : After thyroidectomies it is recommended to perform a laryngoscopy to detect the possible laryngeal edema and nerve palsies (1-2). The goal of this prospective study was to compare three different methods of examination : direct (DL), indirect (IL) and flexible (FL) laryngoscopies.

Materials and methods : three hundred patients operated for thyroidectomy have been studied. After tracheal extubation, the patients were divided into two consecutive groups. In group I (n=200) we evaluated the efficiency of DL. In group II (n=100) we compared the efficiency, the duration, the easiness (+,±,-), and the side effects of the three methods of laryngeal examination. In each patient, the same anesthesiologist performed : DL 15 min after tracheal extubation, IL 15 min later and FL 15 min later (Olympus, LF-1). The efficacy of the laryngeal examinations was assessed by the ability to visualize the larynx on a scale 1-4 as described by Cormack and Lehane (3). The data were analysed using Chi-square test for the efficiency, Anova and Newman-Keuls tests for the duration, easiness and side effects, with p < 0.05 as significant.

Results and (discussion) : Grade 3 and 4 of Cormack and Lehane did not allow a sufficient laryngeal view to detect a glottic dysfunction. DL was ineffective in, respectively, 28% and 16% of the patients in group I and group II. With IL, failure occurred in 27% of the patients in group II. With FL, failure was limited to 1%. The duration of the three procedures was clinically similar (means-IL : 2 min, FL : 2.3 min and DL : 2.6 min), with DL slightly longer than IL. However, FL was easier to perform than DL and IL (+ = 96.5% versus 65% and 55%). The greatest cardiovascular variations were observed during DL. Systolic, diastolic, mean blood pressure (BP) and HR were both significantly higher with DL than with IL and FL. These side effects of FL consist of a slight increase in both HR (4 ± 7 beats per min) and systolic BP (3 ± 11 mmHg).

Conclusion : This study points out the flexible fiberoptic laryngoscopy as the best method for laryngeal examination after thyroidectomy. It is the most efficient, the easiest to perform and its side effects are not different from those of IL.

A.67

DAY 0 OR DAY 3 LARYNGOSCOPY AFTER THYROIDECTOMY ?

Louis Lacoste, Jérome Karayan, Daniele Thomas, Thierry Vallet, Jacques Fusciardi

Departments of Anesthesiology and Ear, Nose
and Throat Surgery, Jean Bernard Hospital,
86021 Poitiers, France.

Background and goal of study : After thyroidectomy, the anesthesiologist usually performs a laryngoscopy to detect laryngeal edema and nerve palsies. However the reliability of this immediate examination has been criticized (1). The goal of our prospective study was to compare the results collected by anesthesiologists on day 0 with the ones collected by the Ear, Nose and Throat (ENT) team on day 3.

Materials and methods : Six hundred and seventy four consecutive patients operated for thyroidectomy have been studied. After tracheal extubation, the patients underwent a laryngeal examination. On day 0, anesthesiologists used a direct laryngoscopy (DL) for the first 221 patients, and a flexible fiberoptic laryngoscopy (FL) for the following 463 patients. On day 3, all these patients were re-examined by the ENT team. After both examinations, vocal cord palsy and paresy (P) were recorded. For the analysis we left out the cases where the larynx could not be seen. Then we looked for the total number of P for the cumulated examinations (PO+P3). Next we analysed the evolution of P between day 0 and day 3 : how many of them disappeared (P3-), how many appeared (P3+), how many remained identical (P0=P3) and how many were recorded opposite (P0≠P3) ? Finally, we determined the value of day 0 examination achieved by the anesthesiologist.

Results and discussion : Inadequate laryngeal visualization accounts for the exclusion of 64 patients (DL:61, FL:2 and ENT:1). As a result, the records of 610 patients could be analyzed. The results are the following : P0+P3=92 (15%), P3-=21 (3.4%), P3+=25 (4.1%), P0=P3=40 (6.5%) and P0≠P3=6 (1%). Day 0 examination allows the detection of P3-, P0=P3 and P0≠P3. This concerned 67 cases representing 11%. Two high-risk patients were immediately detected. Day 3 examination allows the detection of P3+, P0=P3 and P0≠P3. This concerned 71 cases representing 11.6%. Our study confirms that P can be delayed after extubation (2). This occurred in 27.2% of P0+P3.

Conclusion : Laryngoscopy, on day 0, after thyroidectomy remains mandatory. Its rate of P detection is a good one, 73%. This permits a selection of high-risk patients. Since, 27% of P appeared secondarily, day 3 examination should be maintained though.

LARYNGEAL FUNCTION AS ASSESSED BY TUSSOMETRY FOLLOWING TOPICAL ANAESTHESIA

R P Mahajan, G E Murty, P Singh, A R Aitkenhead
University Department of Anaesthesia, Queen's Medical Centre, Nottingham

Background and goal of study: Tussometry is a new non-invasive method of assessing laryngeal function which allows the assessment of laryngeal function by analysis of the airflow waveform produced by a voluntary cough. A normal wave is displayed as cough flow rate (l min^{-1}) against time (ms) and shows a rapid rise to a peak - the cough peak flow rate (CPFR). The time taken to reach CPFR, the peak velocity time (PVT), correlates with vocal cord function [1] and is potentially a useful indicator of laryngeal function in patients undergoing anaesthesia [2]. There is a paucity of data indicating motor function of the vocal cords following topical anaesthesia. We have employed tussometry to determine whether or not topical anaesthesia has any effect on motor function of the vocal cords.

Materials and methods: After baseline measurements of CPFR and PVT, five healthy volunteers, four males and one female (mean age 37.2 yr (range 31-52), mean weight 77.4 kg (range 60-88) and mean height 1.77 m (range 1.7-1.85)) received topical anaesthesia of the nose by a nasal swab soaked in 4% cocaine. Indirect laryngoscopy was performed and the larynx was anaesthetised topically using ten metered dose sprays of lignocaine (100 mg). A fibreoptic laryngoscope was then passed nasally to visualise the larynx. The vocal cords were touched with the scope and if no coughing occurred, the scope was removed and repeat measurements of CPFR and PVT were made.

Results and discussion: All volunteers had excellent anaesthesia of the larynx. No coughing was elicited on fibreoptic laryngoscopy even when the vocal cords were deliberately touched. However, on voluntary coughing, topical anaesthesia had no effect on PVT, indicating normal vocal cord function (Table). All subjects had great difficulty in swallowing.

Table. CPFR and PVT following topical anaesthesia

	CPFR (l min^{-1})		PVT (ms)	
	Before	*After*	*Before*	*After*
Mean	701.6	649.0	28.6	29.4
SD	190.2	100.1	5.9	4.4

Conclusion: Our results indicate that topical anaesthesia of the larynx does not impair voluntary motor function of the vocal cords.

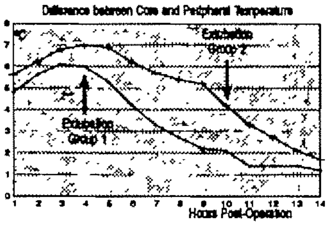
CORE-PERIPHERAL TEMPERATURE DIFFERENCE IN EARLY VS LATER EXTUBATION AFTER CORONARY ARTERY SURGERY.

P. Knapik, J.B. Richardson, I. McLellan
Department of Cardiothoracic
Anaesthesia, Groby Road Hospital, Leicester, U.K.

BACKGROUND AND GOAL OF THE STUDY: Increasing popularity of coronary artery surgery has led to a reappraisal of the need for prolonged postoperative respiratory support after uncomplicated hypothermic cardiopulmonary bypass. Early extubation after open heart surgery in selected patients decreased the core-peripheral temperature gradient and therefore shortened the rewarming period. Testing this observation is the aim of this study.

MATERIAL AND METHODS: Fifty patients who underwent uncomplicated coronary artery bypass surgery and were extubated 4 hours(group I, n=25) and 10 hours (group II, n=25) after termination of cardiopulmonary bypass (CPB) were studied postoperatively. All the patients were cooled to 28°C. Statistical analysis of postoperative core and peripheral temperatures as well as important entry criteria was performed.

RESULTS AND DISCUSSION: Patients extubated 10 hours after weaning from CPB had significantly lower initial core temperatures. The differences between the core and peripheral temperatures were not significant up to the fifth postoperative hour and then became significant with group I rewarming quicker than group II as seen below.



CONCLUSION: Earlier extubated patients with higher initial core temperature are warming up quicker peripherally after uncomplicated coronary artery surgery.

EFFECTIVENESS OF CORE WARMING ON NET TRANSFER OF BODY HEAT ACROSS THE SKIN

P Kulkarni, F Carli

Department of Anaesthesia, Northwick Park Hospital and Clinical Research Centre, Harrow, England.

Background and purpose of the study: Body heat loss can occur during anaesthesia and surgery. Residual hypothermia at the end of surgery can represent a major metabolic load in the high risk population such as elderly with poor cardiovascular reserves.

The effectiveness of measures aiming to attenuate the intraoperative fall in body temperature is assessed by the capacity to maintain core temperature within normal limits and to attenuate the loss of body heat across the skin.

Patients and methods: Thirty elderly patients (age range 60-88 years), otherwise healthy, scheduled for elective total hip replacement, were randomly allocated to 3 groups: group A (control, n=10) with no active warming, group B (hot water humidifier, set at 40°C at mouth level, n=10) and group C (oesophageal warming device, set at 40°C). Premedication was with papaveretum and general anaesthesia consisted of thiopentone, vecuronium, enflurane, N_2O/O_2. Operating theatre ambient temperature was between 18.7 and 21.8°C. Body temperature was recorded in the aural canal (core) and at 15 skin surface sites (mean skin calculated from unweighed formula) before induction of anaesthesia and at the end of surgery and anaesthesia.

Results and discussion: Core temperature fell significantly in group A and C by 1.9 and 1.3°C respectively ($p<0.01$). On the contrary, there was a fall of 0.3°C in the group B (humidifier) (NS). In the latter group mean skin temperature increased from a mean of 34.05°C (SD, 0.31) to 34.21°C (SD, 0.3), whilst in group A, it fell from 33.6° C (SD, 0.8) to 32.5°C (SD, 0.7). In group C (oesophageal warming device) there was a mean fall of 0.2°C in mean skin temperature.

The results of this work show that body heat conservation in elderly patients having hip arthroplasty in a cold environment, is obtained by using hot water humidifier in the anaesthetic circuit.

EFFECT OF PREMEDICATION WITH NIFEDIPINE ON INTRAOPERATIVE HYPOTHERMIA

Vassilieff N*, Rosencher N,* Sessler D.I.***, ConseillerCh* Lienhart A.**

Departments anaesthesia and intensive care COCHIN *and St Antoine** hospitals Paris FRANCE
Department of anesthesia ,University of California San Fransisco***U.S.A.

Introduction: Initial hypothermia is mainly due to redistribution of heat between peripheral and core compartments[1]. In a preliminary , retrospective study Nifedipine, a calcium blocking agent, given days before anaesthesia, has been shown to reduce the initial hypothermia[2] We present a new prospectived and randomized study done in order to confirm these results without statistical bias.

Methods: After obtaining informed consent, 30 patients (ASA 1 or 2) scheduled for total hip arthroplasty were randomly divided into 3 groups. 10 patients received 20 mg Nifedipine long acting orally 12 hours before surgery then 10mg 1h30mn before induction (NPm group). 10 patients received 10mg Nifedipine sublingual immedlatly before induction of anaesthesia (Nind group). 10 patients received no Nifedipine(C group). Core temperature (T core) was continuously measured using tympanic and esophageal probes. Skin T were measured at 5 sites every 10 min for the same periods and mean skin T (MST) calculated. Heart rate and blood pressure were monitored every five minutes. Results (means ± SEM) were compared using ANOVA, modified t-test or Fisher's exact test as required.

Results: The three groups did not differ in age, weight, operating room T ,heart rate ,blood pression and duration of anaesthesia. During the 30 min following induction of anaesthesia, Tcore decreased in the three groups but hypothermia developed less rapidly in the NPm group than in the other group (fig.1.)The final part of the curves are almost parallel.At the end of surgery,Tcore is lower in Nind group (33.43±0.31°C)and in Cgroup(33.58±0.35°C),than in NPm one (34.52±0.35°C). MST remained stable during the surgery in the C group while it increased until the 40th min in the two Nifedipine groups.

Discussion: These results indicate that Nifedipine in normal subjects, given many hours before anaesthesia, reduces core hypothermia .It is probably due to heat redistribution hours before induction. An effect on thermoregulation mechanism is unlikely since the decrease in T core is similar in C group and Nind group.

PREOPERATIVE SKIN-SURFACE WARMING REDUCES INTRAOPERATIVE HYPOTHERMIA.

Camus Y, Delva E, Lienhart A.

Department of Anaesthesia and Intensive Care
Saint Antoine Hospital, Paris, France

Introduction: Induction of anaesthesia is followed by a rapid decrease in core temperature which largely results from redistribution of heat from the core to the cooler periphery.[1] Decreasing the central-peripheral temperature gradient before induction by skin-surface warming largely prevents initial hypothermia in volunteers.[2] The aim of this study was to evaluate the efficacy of preanaesthesia skin-surface warming in reducing intraoperative hypothermia under surgical conditions.

Methods: After informed consent and institutional approval,16 ASA I-II patients, scheduled for laparoscopic cholecystectomy, were randomly divided into 2 groups. 8 patients were preoperatively covered up to the shoulders with an air blanket attached to a forced-air warmer Bair Hugger set at high (≈ 43° C) during 60 min (prew.) while 8 other patients were not (cont.). No special precautions were taken intraoperatively to avoid hypothermia. Core temperature (T) was continuously recorded using a tympanic probe, preoperatively during 1 h (preop) then intraoperatively. Skin T were measured at four sites every 15 min for the same periods and mean skin T (MST) calculated.[3] Results (means ± SEM) were compared using ANOVA, modified t-test or Fisher's exact test as required.

Results: The two groups did not differ in age, weight, operating room T and duration of anaesthesia (128 ± 7 min). Main results are shown in the table and the figure.

Table	MST (° C) end proop	Core T (° C) end preop	Core T (° C) 60 min Intraop
Cont.	34.7 ± 0.3	36.9 ± 0.2	36.0 ± 0.1
Prew.	37.0 ± 0.2 ★	37.2 ± 0.1	36.6 ± 0.1 ★

★ = $p < 0.05$ vs control group.

At the end of surgery core T was 36.1 ± 0.1° C in the prew. group *vs* 35.7 ± 0.1° C in the cont. goup ($p < 0.05$).

Discussion: Preoperative skin-surface warming significantly minimized the initial decrease in core T. This result is in agreement with the importance of internal heat redistribution during the early phase of anaesthesia. It was also sufficient to significantly reduced core hypothermia until the end of laparoscopic surgery lasting ≈ 2 hours.

AN INVESTIGATION INTO THE EFFECT OF PASSIVE AND ACTIVE CUTANEOUS WARMING DEVICES ON INTRAOPERATIVE BODY TEMPERATURE IN ELDERLY PATIENTS

J Bennet, V Ramachandra, F Carli

Department of Anaesthesia, Northwick Park Hospital and Clinical Research Centre, Harrow, England

Background and purpose of the study: Hypothermia is an inevitable consequence of anaesthesia and surgery, and age represents one of the most important factors contributing to a fall in intraoperative body temperature. Providing thermoneutrality during anaesthesia has metabolic and physiological advantages for the elderly patient. Since most of heat is lost through the skin,prevention of cutaneous heat loss might attenuate the fall in central temperature during surgery. The purpose of this study was to assess the effectiveness of skin passive and active warming on maintenance of intraoperative nomothermia.

Patients and methods: Twenty one elderly patients (age range 62-85 years) scheduled for elective hip replacement were randomly allocated to 3 groups of 7 patients each. Group A (control) received no warming, whilst patients in group B (passive warming) were covered with metallised plastic sheet (Thermodrape). In group C (active warming) forced warm air system (Bair-Hagger) was implemented. Ambient temperature in the operating theatre was between 18.4 - 21.1°C. Patients were premedicated with papaveretum, and general anaesthesia was with thiopentone, vecuronium, enflurane, $N_20/0_2$. Core temperature (aural canal thermocouple probe) was measured before induction of anaesthesia and at the end of surgery and anaesthesia. Duration of surgery ranged between 110-175 min.

Results and discussion: Core temperature decreased significantly in the control group (A) from a mean value of 36.6°C (SD, 0.4) to 35.2°C (SD, 0.4) and in passive warming group (B) from 36.8°C (SD, 0.4) to 35.6°C (SD, 0.5) ($p<0.001$). On the contrary, in the active warming group (C) there was a small fall in core temperature throughout surgery, from 36.6°C (SD, 0.3) to 36.2°C (SD, 0.4). These preliminary results show that application of active warming on the exposed parts of the body can significantly attenuate the fall in core temperature and prevent cutaneous heat loss in a selected population of elderly. It remains to be seen whether an extended application of this system to major abdominal/thoracic syrgery maintains perioperative normothermia.

A.74

FENTANYL, AS PETHIDINE, INHIBITS POST ANAESTHESIA SHIVERING

Pascal Alfonsi, Jean-Marc Hongnat, Claude Lebrault, Marcel Chauvin

Department of Anaesthesia, Hopital Ambroise Paré, Boulogne, France

Background and goal of study: Several studies show that pethidine inhibits the Post-Anaesthesia Shivering (P.A.S.) (1). Inversely, other opiates fail to do it (1). The pethidine's efficiency may be the result of its local anaesthetic properties (2). An other reason is that, in the previous studies, the authors did not compare the drugs with an equipotent dosage. The goal of this double-blind controlled study was to compare the effects of pethidine (P), fentanyl (F) and lidocaine (L), versus placebo (C), on P.A.S. .

Materials and methods: In recovery room, after a general anaesthesia, 40 patients with a physical status ASA 1 or 2 were included. They all presented shiverings associated with a tympanic temperature below 36°C. None presented an allergy for local anaesthetic. The patients received: P (n=13; 0.85mg/kg) F (n=13; 1,7 mcg/kg) L (n=7; 1 mg/kg) C (n=7; Ringer-Lactate's solution). All the solutions were injected in a 10 ml volume. At the 15th min. (T15), the patients who were still shivering were excluded. Shiverings were evaluated all the time by the same investigator.

Results and discussion: The patient's and anaesthetic's charateristics are summarized in Table 1. At T15, 100% in C still presented P.A.S., 86% in L, 23% in F($p<0.01$ vs C) and 8% in P($p<0.001$ vs C). When the patients had stopped shivering, all of them were hypothermic (35.1±0.6°C in P and 35.9±0.5°C in F). From T15 to T45, 60% of patients receiving F and 8% receiving P had again presented P.A.S.

Conclusion: Our results show that fentanyl, as pethidine inhibits P.A.S. In the previous studies (1), fentanyl have been probably used with an insufficient dosage. This result confirms that the effects of opiates on shiverings are mediated by opiates receptors (3).

A.75

MODIFICATION OF THE RENIN-ALDOSTERONE AXIS DURING ORTHOTOPIC LIVER TRANSPLANTATION

De los Ríos J., Iribarren MªJ, Monedero P, García-Pedrajas F, Arroyo JL
Anesthesiology Department. Clínica Universitaria. School of Medicine. University of Navarra. Pamplona. Spain.

Introduction: Several studies have demonstrated that the activation of the renin-angiotensin-aldosterone (RAA) system is an important cause of renal sodium retention in cirrhosis. We have evaluated the changes in plasma renin activity (PRA), plasma aldosterone (PA) concentrations and urinary excretion of sodium (mEq/24 h) (UENa) in patients undergoing orthotopic liver transplantation (OLT) with preoperative high levels of renin and aldosterone and low renal sodium excretion.

Methods: We studied 16 patients with main diagnosis of cirrhosis, scheduled for OLT who fulfilled all criteria required by the protocol of our institution. Renal function profile was included within preoperative study. No patient was on antihypertensive therapy. Eleven patients were treated with spironolactone and 2 patients were with low sodium diet. No patient was azotemic and none had intraoperative events in terms of hemodynamic stability and renal function. A standard anesthesia technique was used. We measured PRA and PA before surgery and in the morning of the next four postoperative days. All patients were studied following our postoperatory protocol for OLT.

Results: In the four postoperative days the PRA and PA values were significantly lower than basal value. There were no differences in cardiac output and hemodinamic parameters between preoperative and the first postoperative day. On the other hand, UENa was significantly raised in the postoperative days compared with basal values.

	BASAL	DAY1	DAY2	DAY3	DAY4
PRA ng/ml/min	10.7±8.2	7.4±11	1.3±1.2*	1.2±0 8*	0 6±0.7*
ALD ng/ml	628±525 2	202±210.5*	65.5±40 1*	64±44 4*	54.8±32.8*
UENa meq/ 24h	74.5±48.3	259±146*	375±168*	418 2±189*	341 1±120*
CO L / mn	9±4 05	9 5±2.7	8 9±2.2		
SVR dyn s cm-5	794±422	631±228	810±210		
MAP mmHg	83±15	80±12	85±17		
PCWP mmHg	11±2 9	13±2.4	13±3.1		

* p<0.05

Discussion: It is concluded that in patients with stimulated RAA system by cirrhosis, a fall in PRA and PA after OLT ocurred postoperatively, which could be interpreted as physiological inhibition of this system due to the fluid volume received during the intraoperative and the four postoperative days. We explain the important natriuresis observed during the postoperative period as a consecuence of the inhibition of the RAA system and other mechanisms which produce renal sodium retention in cirrhosis.

A.76

MEASUREMENT OF SIGMOID INTRAMURAL PH DURING ORTHOTOPIC LIVER TRANSPLANTATION.

Yves Auroy, Marie-Christine Gillon, Henri Bismuth*, Claude Ecoffey.

Département d'Anesthésie - Réanimation et *Service de Chirurgie hépato-biliaire, Hôpital P. Brousse, Université Paris-Sud, 94804 - Villejuif, FRANCE

Background and goal of study: The presence of sigmoid intramural acidosis, as measured by balloon tonometry, has been shown to be predictive of a higher incidence of complications in postoperative patient (1). A relationship was found between low sigmoid intramural pH (pHi) values were causally related to changes in gut perfusion which can induced ischemic colitis (2). During orthotopic liver transplantation (OLT) a decrease in splanchnic perfusion can occurred during the anhepatic phase (3) and we assessed the evolution of the pHi during the different stages of OLT.

Material and methods: Ten patients aged 49 ± 11 yrs (mean ± SD) who underwent OLT were studied. After induction of anaesthesia, a radial artery catheter, a Swan Ganz catheter and a silicone balloon tonometry (TRIP*TS 1001) were placed. The balloon was introduced until the junction between the rectum and the sigmoid colon. The following measurements were performed: mean arterial pressure (MAP, mmHg), cardiac index (CI, $min^{-1}.m^{-2}$), arterial pH (pHa, unit), mixed venous pH (pHv, unit), pHi (unit), and arterial lactate (Lact, $mmol.l^{-1}$). The measurements were assessed during the dissection phase (T1 and T2), during the anhepatic phase (T3) and during the reperfusion phase (T4, T5 T6, respectively one, two, three hours after unclamping the hepatic vessels). The pHi value was calculated with Henderson-Hasselbalch equation with the use of arterial bicarbonates. All the results are expressed as mean ± SD and a statistical analysis ($p < 0.05$ significant) was performed with ANOVA following by Fischer test.

Results and discussion : A veno-venous bypass was used in 8 patients. One patient received 200 ml of molar sodium bicarbonate after the reperfusion phase and the values of pHi were excluded of the analysis. The results are summarized in the table:

mean (SD)	T1	T2	T3	T4	T5	T6
PAM	101	103	104	92	92	99
	(15)	(15)	(21)	(17)	(18)	(20)

	(0.04)	(0.03)	(0.03)	(0.04)	(0.06)	(0.03)
pHi	7.34	7.32	7.25*	7.33	7.34	7.33
	(0.08)	(0.09)	(0.08)	(0.08)	(0.10)	(0.10)
Lact	1.9	2.3	3.7*	3.9*	3.1	2.5
	(0.7)	(1.0)	(0.9)	(1.0)	(0.7)	(0.1)

* $p < 0.05$ vs other measurements

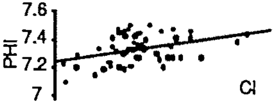

Figure: Relationship between pHI (unit) and CI ($l.min^{-1}.m^{-2}$)
$y = 0.03 x + 7.2$
($n = 54$, $r = 0.4$, $p< 0.01$)

Conclusion: The transient changes of pHi during OLT indicated probably a decrease in gut perfusion, due in part to the decrease in CI, without ischemic colitis complication. Further measurements should be taken after the reperfusion phase in order to detect an possible ischemic colitis.

A.77

CHANGES IN BLOOD LACTATE, TOTAL BODY OXYGEN DELIVERY AND CONSUMPTION DURING LIVER TRANSPLANTATION

Carrera J, Monedero P, Iribarren MJ, de los Ríos J, Panadero A

Department of Anaesthesiology, Clínica Universitaria, School of Medicine, University of Navarra, Pamplona, Spain

Introduction: The liver, perfused by approximately 25 per cent of the cardiac output, has a large oxygen consumption and plays a central role in lactate metabolism for acid-base homeostasis. The O2-uptake and lactate concentrations during 36 orthotopic liver tranplantations (OLT) were studied to know their changes during this procedure.

Methods: Cardiac output and central venous oxygen saturation were measured by an oximetric-type pulmonary artery catheter, after anaesthetic induction (basal sample, B) and during each of the three operative periods (I: dissecting period-preanhepatic; II: anhepatic phase; III: after reperfusion of the new liver): 60 and 120 minutes after incision (IA, IB); 30 minutes after removal of the liver (IIA); and 10, 60 and 120 minutes after graft reperfusion (IIIA, IIIB, IIIC). Samples of arterial blood were taken simultaneously for lactate and hemoglobin blood concentration and arterial oxygen saturation. The index of total body oxygen delivery (IDO2) and consumption (IVO2) was calculated.

Results and Conclusions: Results are shown in table I.

The IVO2 decreased after removal of the liver (IIA), and increased after reperfusion (IIIA, IIIB, IIIC). The level of IVO2 was higher after reperfusion (IIIA) than in the dissecting period (IA, IB).

Lactate levels increased during the surgical procedure, mainly during the anhepatic phase (IIA), and began to decrease 2 hours after reperfusion (IIIC). Six patients with bad postoperative liver function (3 of them required retransplantation) showed higher lactate levels than patients with good evolution (Lactate IIIB: good evolution 5.6 (1.8) versus bad evolution: 8.3 (2.1); $p<0.05$ Mann-Whitney U). (Lactate IIIC: good evolution 5.2 (2.0) versus bad evolution: 7.6 (0.7); $p<0.05$ Mann-Whitney U). We conclude that lactate concentrations may have a pronostic value in OLT.

Table I : IDO2, IVO2 and lactate during OLT: mean (SD)
(ml/min/m2) (mM/L)

	B	IA	IB	IIA	IIIA	IIIB	IIIC
IDO2	640 (213)	736 (228)	705 (224)	413 (142)	943 (313)	788 (266)	733 (168)
IVO2	109 (41)	103 (30)	93 (28)	81 (62)	131 (51)	121 (35)	117 (32)
Lactate	1.8 (1,3)	2.1 (1,1)	2.6 (1,0)	4.5 (1.6)	5.8 (1.7)	5.9 (1.9)	5.4 (2.0)

A.78

OXYGEN CONSUMPTION IS DEPENDENT UPON OXYGEN DELIVERY IN CIRRHOTICS UNDERGOING LIVER TRANSPLANTATION

Pasquale Piccinni, Antonio Tripepi, Lorenzo Rossaro*, Francesco De Zen, Antonino Pierri.

Servizio di Anestesia e Rianimazione,
*Gastroenterologia, Universitá di Padova, Italy

Background and goal of study: Hepatic failure secondary to chronic liver disease is associated with an hyperdynamic state characterized by an increased cardiac index, low systemic vascular resistance, and abnormal tissue oxygenation[1]. The relationship between oxygen uptake (VO_2I) and systemic oxygen delivery (DO_2I) in cirrhotic patients is not known. The aim of the present study was to evaluate such a relation (VO_2I/DO_2I) during each phase of orthotopic liver transplantation (OLTx).

Materials and methods: We performed a complete hemodynamic study in ten adult cirrhotic patients who underwent OLTx, with constant temperature, stable hemoglobin levels during homogeneous anaesthesiological and technical procedures, which included also venous-venous bypass. We used a rapid response thermodilution pulmonary artery catheter (Swan-Ganz, 93A-431H-7.5F, Baxter) and a gas analyzer (Oxymetrix 3 Computer, Abbott) which provided continuous measurements of venous oxygen saturation ($S\bar{v}O_2$) and thereby enabled us to calculate VO_2I and DO_2I. Hemodynamic profiles were determined at different times during OLTx: (1) basal, (2) 30 min before and (3) during the anhepatic phase, (4) 5 min and (5) 30 min after reperfusion of the graft.

Results and discussion: A direct linear correlation was observed during each phase of OLTx between VO_2I and DO_2I ($R=0.7393$, $p<0.01$), demonstrating a strong dependance of oxygen consumption upon oxygen delivery.

Conclusion: We hereby report, for the first time, the dependance of oxygen consumption upon oxygen delivery in cirrhotic patients undergoing liver transplantation. This abnormal finding must be further evaluated and confirmed on a larger series. Meanwhile, our observations suggest the important role of maintaining effective tissue oxygenation by adequate DO_2I levels during liver transplantation.

A.79

EFFECTS OF DESMOPRESSIN (DDAVP) SUPPLEMENTATION IN BRAIN DEAD ORGAN DONORS (BDOD) ON EARLY RECIPIENT RENAL FUNCTION

Richard Guesde, Salda Ourahma, Bruno Riou, Pierre Viars

Department of Anaesthesia and Intensive Care,
Groupe Hospitalier Pitié-Salpêtrière, Paris, France

Background and Goal of the Study : Treatment of central diabetes insipidus (DI) is required during BDOD care to avoid major metabolic disturbances and premature cardiac standstill Replacement of massive water and potassium losses is difficult to achieve and vasopressin-related post-transplantation renal dysfunction has been suggested. The use of DDAVP instead of vasopressin in BDOD has not yet been assessed.

Patients and Methods : Retrospective data concerning 42 consecutive BDOD (15 of which received DDAVP to decrease hyperdiuresis) were studied. and those from 78 of the 80 corresponding recipients (26 of which benefited from DDAVP-supplemented kidneys). obtained by queries. were analyzed up to the fifth posttransplantation day. Data are expressed as mean ± sd

Results :Both groups of BDOD were similar with respect to sex ratio. age. and occurrence of hypotension. 14 of the 15 DDAVP donors required dopamine (7.9 ± 5.0 μg/kg/min) versus 19 of the 27 others (7.0 ± 4.4 μg/kg/min) in order to maintain adequate haemodynamics. this difference did not reach statistical significance. Maximum urine output was higher in the DDAVP group (1530 ± 814 vs 1001 ± 730 ml. $p<0.01$). while last urine output before harvesting was similar in both groups (900 ± 1221 vs 628 ± 642 ml.). All BDOD but two in the non-DDAVP group became multiorgan donors.

Both groups of recipients were similar with respect to factors influencing early renal outcome : age. occurrence of diabetes and hypertension. cold and warm ischaemia times. number of HL-A.-B.-DR mismatches. preoperative serum creatinine levels and need for early reoperation. Immediate urine output was higher in the DDAVP-recipient group during the 4th and 5th posttransplantation hours. Daily serum creatinine decay rate was not different between groups. Posttransplantation needs for dopamine and furosemide. occurrence of acute tubular necrosis requiring haemodialysis (7/28 vs 14/50) were not different

Conclusions · Kidneys harvested from DDAVP treated BDOD showed a good early renal recovery. similar to those from unsupplemented donors DDAVP given to decrease major polyuria in BDOD did not seem to be detrimental to early renal transplant function. The lack of vasopressin-associated vasoconstriction may explain this result. A prospective randomized study is now undertaken to demonstrate that the beneficial effect of DDAVP on BDOD care is also beneficial to recipient renal function.

A.80

FIBEROPTIC BRONCHOSCOPY IN BRAIN DEAD ORGAN DONORS.

Bruno Riou, Richard Guesde, Yves Jacquens, René Duranteau, Pierre Viars.

Department of Anesthesiology, CHU Pitié-Salpêtrière,
University Paris VI, Paris, France.

Background and goal of the study: The quality of the donor lungs is one of the most significant predictors of the clinical outcome of pulmonary and cardiopulmonary transplantations. Criteria for selecting lung donors include normal chest X-ray and adequate gas exchange, but a normal fiberoptic bronchoscopy (FO) is not always required. We conducted a prospective study of FO in brain dead donors scheduled for a multiple organ procurement.
Patients and methods: Criteria for inclusion were : 1/brain death ; 2/multiple organ procurement was scheduled ; 3/FO (Olympus BF10) could be performed by a highly trained bronchoscopist before going to the operating room. Chest X-ray was performed in a supine position and analyzed by a blind observer (normal/abnormal), arterial blood gas analysis was performed under an FiO_2 of 100 %. The following FO diagnosis could be made: 1/normal; 2/inhalation of blood; 3/inhalation of gastric contents; 4/pulmonary contusion; 5/purulent bronchial secretions. Cardiac evaluation was performed using a Swan-Ganz catheter or transesophageal echocardiography.
Results: 72 brain dead donors were included, mean age 38±13 yrs. Chest X-ray was normal in 37 (51%) donors, and the PaO_2 was greater than 400mmHg with an FiO_2 of 100 % in 34 (47%) donors. FO was normal in only 24 (33 %) donors. In the remaining 48 donors, inhalation of blood (n=17) or gastric contents (n=16), pulmonary contusion (n=5), or purulent bronchial secretions secretions (n=9) were noted. In the 26 donors with normal chest X-ray and a PaO_2 greater than 400 mmHg with an FiO_2 of 100%, FO was abnormal in 10 (38%) donors. In 33 donors with a Swan-Ganz catheter, the arteriovenous difference in oxygen content (2.4±0.8mlO2/100ml), and pulmonary shunt (0.30±0.11, range 0.13-0.49) were measured. In the 15 donors with a PaO_2 greater than 400mmHg, pulmonary shunt was 0.23±0.07, range 0.13-0.35.
Conclusion: Chest X-ray and arterial blood gas analysis are not sufficient, and FO should be routinely performed to select lung donors. In donors with a normal FO, measurement of pulmonary shunt, and not only PaO_2, should be performed to assess pulmonary gas exchange.

A.81

TOTAL INTRAVENOUS ANAESTHESIA (TIVA) WITH PROPOFOL AND ALFENTANIL FOR RENAL TRANSPLANTATION

M. Kirvelä, A. Yli-Hankala, L. Lindgren

Department of Anaesthesia, IV Clinic of Surgery,
Helsinki University Hospital, Helsinki, Finland

The pharmacokinetics of propofol (1) and alfentanil (2) are similar in uraemic and healthy patients. We compared TIVA with propofol and alfentanil to balanced anaesthesia (BA) for renal transplantation.

Patients and methods: 30 uraemic patients undergoing renal transplantation were anaesthetized with either TIVA (15 pts, mean (SD) age 37(11) yr, weight 67(9) kg) or BA (15pts, 42(13) yr, 72(11) kg). TIVA was induced with propofol 2-2.5 mgkg^{-1} and alfentanil 0.03 mgkg^{-1}. Propofol 12 mgkg^{-1}h^{-1} and alfentanil 0.07 mgkg^{-1}h^{-1} were started immediately after induction. Thereafter the infusion rates were adjusted as needed. Ventilation was with oxygen in air. BA was induced with thiopentone 4 mgkg^{-1} and fentanyl 3 µgkg^{-1} and maintained with isoflurane in nitrous oxide in oxygen and fentanyl 1.5 µgkg^{-1}h^{-1}. Vecuronium was used for muscle relaxation in both groups. Heart rate (HR), systolic (SAP) and diastolic (DAP) blood pressures were recorded at 5 min intervals. Antihypertensive treatment was given if SAP was >180 mmHg or DAP >110 mmHg over 15 min. Ephedrin was given if SAP was <100 mmHg. Central venous pressure was kept above 4 mmHg. Time interval from the discontinuation of anaesthetics to extubation was recorded. Recovery was assessed with Maddox wing apparatus and by scoring system hourly. Oxycodone and droperidol recquirements were recorded.

Results: Mean infusion rates for propofol and alfentanil were 10 (1.8) mgkg^{-1}h^{-1} and 70 (9) µgkg^{-1}h^{-1} respectively. Vecuronium 35(14) and 19(16) mgkg^{-1}h^{-1} was needed during TIVA and BA, resp.($p<0.05$). After induction of anaesthesia, HR, SAP and DAP were significantly higher in the BA group ($p<0.01$). Thereafter, SAP and DAP tended to be higher in the TIVA group, especially at the end of anaesthesia ($p<0.05$). No difference in HR was found between the groups. Two patients in the TIVA group needed antihypertensive therapy. Two patients in the TIVA and 3 patients in the BA group needed treatment for hypotension. There were no differences in the recovery parametres or oxycodone recquirements. Five patients in the BA and none in the TIVA group needed droperidol for nausea ($p<0.05$).

Discussion:: To control renal hypertension during TIVA, larger amounts of propofol and alfentanil were needed and slower recovery was observed than in previous studies in ASA 1-2 patients (3). Significantly more vecuronium was needed than with BA. TIVA had no clinical advantages over BA. Supplementation of TIVA with nitrous oxide could diminish the need for propofol and alfentanil leading to better recovery.

PREVENTION OF ACUTE TUBULAR NECROSIS BY VOLUME LOADING IN KIDNEY TRANSPLANTATION

Catherine Mouquet, Jacqueline Luciani,
Marc-Olivier Bitker, Pierre Viars.
Departments of Anaesthesiology and Urology
CHU Pitié - Salpêtrière, Paris, France.

Background and goal of study: Acute tubular necrosis (ATN) after kidney transplantation (KT) decreases the probability of graft's survival. The efficacy of volume loading (VL) in preventing ATN has been previously shown. (1) However, deleterious hemodynamic effects of VL have been reported in these high risk patients. (2) Accordingly, we investigated haemodynamic response to VL in chronic renal failure (CRF) patients during KT.

Patients and methods: 16 CRF patients, mean age 32 ± 8 yrs, who benefited from a KT, were studied. Heart rate (HR, bpm), mean arterial pulmonary pressure (MPAP, mmHg), capillary wedge pressure (CWP, mmHg) and cardiac output (CO, l.min^{-1}) measured using a Swan-Ganz catheter, and non invasive mean arterial pressure (MAP, mmHg) were measured before (CONT) and after induction (IND), before (PREX) and after (POSTX) the period of vessel clamping, at the end of surgery (END), and at the first postoperative day (D1). Data are mean ± SD.

Results : The mean VL during KT was 3950 ± 950 ml. Data are summarized in the table. Immediate diuresis after KT was observed in 100 % of the cases.

	CONT	IND	PREX	POSTX	END	D1
HR	75±12	70±12	66±10	70±10	72±14	84±12*
MAP	101±20	98±25	99±17	99±22	105±13	108±17*
MPAP	18±9	15±8	26±6*	29±8*	27±7*	25±8*
CWP	12±6	11±4	19±6*	22±8*	20±7*	14±7
CO	8.0±2.2	6.1±1.3	7.5±2.7	8.7±3.3	9.0±3.0	9.8±2.7*

Discussion : These results suggest that VL might be useful in preventing ATN. However VL may be associated with transient but significant increase in cardiac filling pressures. A pulmonary artery catheter monitoring appears useful to control the risk for an acute pulmonary edema in these high risk patients.

A.83

VOLUME LOADING AND HORMONAL FACTORS IN THE PREVENTION OF ACUTE TUBULAR NECROSIS IN KIDNEY TRANSPLANTATION

Catherine Mouquet, Alain Carayon, François Clergue, Jacqueline Luciani, Marc Bitker, Pierre Viars.
Departments of Anaesthesiology, Urology and Biochemistry, CHU Pitié- Salpêtrière, Paris, France.

Background and goal of study : Acute tubular necrosis (ATN) after kidney transplantation (KT) has a deleterious effect on graft survival. The efficacy of volume loading (VL) in preventing this complication can be related to several mechanisms : increase in arterial pressure, graft's arterial blood flow, or atrial natriuretic factor (ANF). We measured ANF (pg.ml^{-1}), aldosterone, vasopressin (AVP, pg.ml^{-1}), and plasma renin activity (PRA, mg.ml^{-1}.h^{-1}) in 12 chronic renal failure patients before and after VL performed during KT.

Patients and methods : A Swan-Ganz catheter was used for measurements of cardiac filling pressures and cardiac output, and a radial artery catheter for arterial pressure. Haemodynamic measurements and blood samples were obtained before (CONT) and after induction (IND), before (PREX) and after (POSTX) the period of vessel clamping, and at the end of surgery (END). Hormonal dosages were determined by specific radioimmunoassays.

Results and discussion : VL induced a significant increase in both cardiac filling pressures and a further increase in ANF plasma levels, which were elevated at the preinduction state. PRA only increased at END without significant change in arterial pressure, probably due to furosemide administration. AVP increased after POSTX and END, without antidiuretic effect (Table).

	CONT	IND	PREX	POSTX	END
ANF	240±147	210±119	736±672*	669±439*	538±325
ALDO	206±329	162±119	203±177	216±141	167±96
PRA	1.9±1.8	1.8±1.7	1.9±1.7	2.8±2.1	3.5±2.9*
AVP	3.3±2.3	3.2±2.2	3.5±2.9	5.9±4.2*	14.9±17.5*

* $p < 0.05$ VS Cont.

All grafts had immediate diuresis and no ATN was noted.

Conclusion : The marked increase in ANF in response to VL suggests that the efficacy of VL in preventing ATN after KT may be related to natriuretic and diuretic effects of ANF and to its potent inhibitory effect on AVP.

A.84

IS THE VASOCONSTRICTIVE EFFECT OF CYCLOSPORINE MEDIATED BY ENDOTHELIN IN KIDNEY TRANSPLANTATION ?

Catherine Mouquet, Alain Carayon, Saïda Ourahma, Marc-Olivier Bitker, Pierre Viars.
Departments of Anaesthesiology, Urology and Biochemistry, CHU Pitié-Salpêtrière, Paris, France.

Background and goal of the study: Endothelin, a vasoconstrictive peptide synthetized by endothelial cells, has been implicated in the vasoconstritive effect of cyclosporine. (1) We measured plasma creatinine and endothelin (ET) levels before and after kidney transplantation (KT) in dialyzed chronic renal failure (CRF) patients to compare ET plasma levels and incidence of hypertension (HT) in patients treated vs non treated with cyclosporine.

Patients and methods: 53 CRF patients (19 women, 34 men), mean age 44 ± 12 yrs, undergoing KT were divided into 2 groups depending or whether or not they were treated with cyclosporine (CYCLO +, n = 22, (CYCLO -, n = 31). Plasma creatinine and ET by specific radioimmunoassay were measured before, 1 day, 1 and 3 months after KT in the 53 CRF patients, and in 20 healthy subjects, . Data are mean ± SD.

Results: Before KT : 26 (49 %) CRF patients were hypertensive. Plasma creatinine was 101 ± 32 mg.l^{-1}, and ET was higher than in healthy patients (5.9 ± 1.6 vs 3.6 ± 1.0 pg/ml^{-1}, $P<0.05$).

After KT : plasma creatinine and the incidence of HT (42 vs 41 %) were similar in both groups, although ET was higher in CYCLO + group (Table).

	Before KT	After KT	1 month	3 months
CYCLO -	5.8±1.2	6.6±1.8	3.8±0.8	3.7±0.8
CYCLO +	6.0±2.1	6.0.±1.4	4.3±0.9*	4.6±1.5*

* : $p < 0.05$ vs CYCLO -

Discussion: ET plasma levels are higher in CRF patients than in healthy patients. Although the improvement in renal function was similar in both groups, ET was higher in patients treated with cyclosporine, suggesting that the vasoconstrictive effect of cyclosporine may be mediated by ET, as previously suggested. (1) However, these higher ET plasma levels were not associated with an increased incidence of hypertension.

A.85

RENAL BLOOD FLOW AND FUNCTION RELATIONSHIP IN RECENT RENAL TRANSPLANTATION IN MAN

L. Jacob, JJ. Chazalet, D. Payen, J. Bedrossian,
P. Teillac, B. Eurin

Department of Anesthesiology and Intensive care, Hôpital Universitaire Saint-Louis, Paris, France.

Renal Blood Flow (RBF) measurements may be of interest to predict renal allograft function (1). Duplex external Doppler ultra-sonography has been used in the identification and differential diagnosis of various causes of renal allograft dysfunction (2). With these techniques RBF value is not available since the artery diameter and the ultrasonic beam incidence angle are not known. Recent advance in Doppler technology, using miniaturized implantable microprobes (3), enables measurements of mean and phasic RBF supplying renal allograft in man. The goal of this study was to evaluate post-operative RBF and function relationship .

Material and methods. After informed consent and local ethical committee approval, 25 patients were studied after cadaveric renal transplantation. Patients were divided in two groups according to the initial function of the graft. Early function (Group I, n=13) was defined as daily urine output > 1000ml during the first 48 h, serum creatinine < 250 $\mu mol.l^{-1}$ at the end of the first week and no dialysis requirement. Group II patients (n=12) had delayed funtion. RBF was measured by pulsed Doppler implantable microprobe. Renal function was assessed by Urine output (Vu) and creatinine clearance (CrCl). **Protocol** Parameters were recorded at D0 and every day until the sixth post-operative day. **Statistical analysis** was performed using ANOVA and a Mann & Whitney test.

RESULTS are summarised in table 1 (Mean ± SD)

DISCUSSION: Renal hemodynamic study showed that : 1° RBFm at D0 was not predictive of the initial graft function. 2° RBFm decreased from D0 to D6 in GII. 3° Pourcelot index increased in both group and was significantly higher in GII suggesting a potent renal vasoconstriction in patients with delayed function.

EFFECT OF RECOMBINANT HUMAN GROWTH HORMONE (HGH) ON PROTEIN METABOLISM IN SURGICAL PATIENTS

F Carli, J Anderson, M Read, D Halliday

Department of Anaesthesia and Nutrition Research Group, Northwick Park Hospital and Clinical Research Centre, Harrow, England

Background and goal of the study: The metabolic response to surgery include weight loss and negative nitrogen balance.

We have investigated the possibility of using anabolic stimuli in combination with low nitrogen/calorie intake to attenuate net protein breakdown and promote body nitrogen retention.

Materials and metods: Sixteen patients undergoing colorectal surgery for excision of tumour were studied. Daily nutritional intake, based on nitrogen 0.1 g kg^{-1} and calories 84 J kg^{-1} was started orally 6 days before surgery and continued parenterally for 6 days after operation. One group (control, n=8) received placebo whilst the other group (HCG, n=8) received a daily s.c. dose of 0.15 IU kg^{-1} of recombinant human growth hormone for 6 postoperative days. Urinary excretion of nitrogen was measured before surgery and for 6 consecutive days after operation. Quadriceps muscle mixed protein synthetic rate was extimated in eight patients using stable isotope L(1-^{13}C) leucine before and 6 days after surgery.

Results and discussion: Urinary nitrogen excretion increased after surgery in both groups, however, the cumulative nitrogen excretion was significantly attenuated in the HGH group compared with the control group (p=0.017). Protein synthetic rate (% h^{-1}) in the quadriceps muscle decreased by 25% in the control group after 6 post operative days, whilst it increased from a mean value of 0.03014 (SD, 0.0063) to 0.042094 (SD, 0.013) in the HGH group. These findings indicate a modulatory role of HGH on protein synthesis and breakdown in stressed patients receiving a hypocaloric nutrition.

A.87

GLYCINE AND ITS METABOLITES DURING AND AFTER INTRAUTERINE YAG LASER SURGERY

M.J. Van Boven, MD, P.E. Pendeville, MD and F.J. Singelyn, MD.

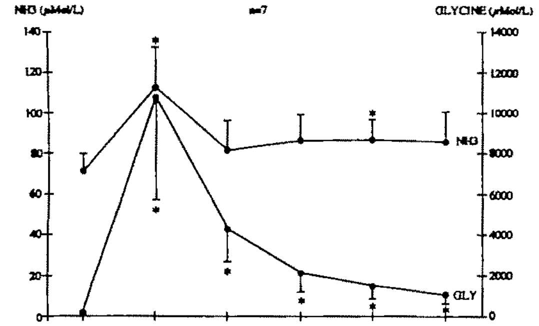
Dept of Anesthesiology, St Luc Hospital, UCL Medical School,
1200 Brussels, Belgium.

Glycine 1.5% solution is used as a distending medium during intrauterine YAG laser surgery (IYAGLS). Very high amounts of glycine solution may be resorbed during the procedure leading to fluid overload, electrolyte dilution and hyperglycinemia. The aim of this study was to determine the levels of glycine and its metabolites during and after IYAGLS.

Methods: After informed consent, seven ASA I-II, artificially menopaused patients were included in this study.IYAGLS was performed under general anesthesia. Intravenous fluid was restricted to 500 ml of Ringer's lactate during the induction period followed by 2 ml $\mathrm{kg}^{-1}\mathrm{h}^{-1}$during and after the procedure. The in and out fluid irrigating fluid balance was monitored by a volumetric technique.Intrauterine pressure was monitored by a pressure transducer connected to the hysteroscope.Hematocrit, serum osmolarity, sodium, potassium chloride, proteins, aminoacids and ammonia (1) were determined before and 30, 60, 120, 180 and 240 minutes after the beginning of the procedure. Oxaliuria was assessed on two 12 hours urine collections taken before and after IYAGLS (2). A Wilcoxon signed rank test was used in order to analyse the biological parameters. Results are expressed as means ± SEM.

Results: Mean irrigant absorption was 1128±254,5ml. Duration of the procedure was 29,7±6,3 minutes. Mean intrauterine pressure was 165±17 mm hg. Serum concentrations of glycine and ammonia are presented in fig 1.

fig.1



Glycine serum concentrations increase massively reaching a 50 (4-100) times the initial values after 30 minutes. Ammonia serum concentrations increase moderately. There is no significant cha in the other studied parameters.No hyperoxaliuria was found the procedure.There is no correlation between glycine serum concentration and infusion pressure or resection time. No symptoms of glycine toxicity were noted.

Conclusion: Massive irrigant absorption may occur during IYAGLS. Beside the risk of fluid overload, glycine absorption may lead to hyperglycinemia and hyperammoniemia (3). As general anesthesia may mask the early signs of glycine overload, we recommend to perform IYAGLS under regional anesthesia and to ensure a good washout of the uterine cavity during the procedure to avoid overpressure.

CARBOHYDRATE DEFICIENT TRANSFERRIN: A NEW COPREDICTOR OF ALCOHOLISM RELATED POSTOPERATIVE COMPLICATIONS?

*T.Hell, *C.Spies, *T.Neumann, §C.Müller

*Department of Anesthesia and Intensive Care, Steglitz
Medical Center, §Department of Clinical Chemistry and
Biochemistry, Rudolf Virchow Medical Center,
Free University of Berlin, Berlin, Germany

Alcohol dependent patients are at risk for increased morbidity during ICU therapy. Since post-OP alcohol withdrawal syndrome (AWS) may induce severe complications, sensitive preoperative evaluation of physical dependence is mandatory. Compared with other conventional parameters (MCV,GGT,ASAT,ALAT) elevated Carbohydrate deficient transferrin (CDT), an isoform of tranferrin, is reported to be a reliable marker[1] of chronic alcohol abuse (50-70 g/d). We investigated whether pre-OP diagnosis of dependence can be improved by determination of CDT.

Fifty male patients with a history of alcohol consumption underwent resection of oropharyngeal laryngeal or oesophageal tumors with subsequent ICU management. Precise history was supplemented by alcoholism-associated questionnaire[2], conventional lab tests (MCV,GGT,ASAT, ALAT) and determination of CDT performed by micro-anion-exchange-chromatography[3] (nl<9mg/l). The pre-OP assessment was validated by occurrence of post-OP withdrawal symptoms. Statistical analysis was performed by MANOVA.

Preoperatively 11 patients were diagnosed as dependent, 13 patients developed post-OP AWS. 15 patients were preoperatively diagnosed as chronic abusers without physical dependence. All dependent patients had elevated CDT (> 9mg/l) except for one. In contrast, no patients who were sober for more than seven days had abnormal CDT levels (fig.1).

CDT can be used as sensitive parameter for chronic alcohol abuse and as reliable copredictor for the occurrence of alcoholism related postoperative complications.

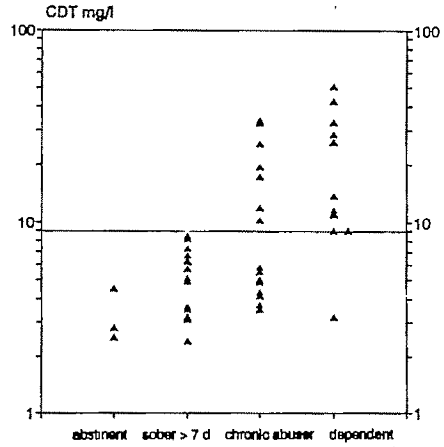

Fig. 1: CDT values in different groups (pathological CDT > 9mg/l)

EFFECTS OF DIAZEPAM ADDITIVES ON THE MONONUCLEAR PHAGOCYTIC SYSTEM

Catalá JC, Carrera JA, Iribarren MJ,
García Pedrajas F, Arroyo JL

Department of Anaesthesiology, Clínica Universitaria, School of Medicine, University of Navarra, Pamplona, Spain

Introduction:

In previous studies we dealt with the possibility that diazepam may reduce the expression of vimentin filaments, phagocytic activity, and the membrane display of HLA DR molecules in human monocytes. In the present in vitro study we have evaluated the possible contribution on these effects of additives contained in diazepam solution (propylene glycol, ethanol and benzyl alcohol) on the expression of vimentin filaments, the phagocytic activity, and the membrane display of HLA DR molecules in human monocytes.

Methods:

The study was performed on centrel blood samples from healthy donnors.

Blood samples were divided into four fractions: three blood aliquots were incubated with additive mixture of diazepam (0.4 mg.10^{-6} monocytes) for 1, 2, and 16 hours. Also, control aliquots were incubated with no additives for 0 (basal, 1, 2, and 16 hours) .

After isolation of human monocytes by the Boyum technique, the membrane display of DR molecules, the expression of immunoreactive vimentin filaments, and the latex particles phagocytosis index were analized by immunofluorescence using monoclonal antibodies.

Results:

All parameter determined decreased significantly ($p<0.01$) after incubation with diazepam additives, and no variations were reported in control monocytes at basal time and at different times.

Additives were found to be strong inhibitors of expression of vimentin filaments, phagocytic activity, and the membrane display of HLA DR molecules after 1, 2, and 16 hours. Although the decrease of this values was of lower magnitud after 16 hours (see Table below). Therefore, we must take into account that the higest diazepam doses administered, the highest doses of additives are given.

Conclusions:

Diazepam additives produce in vtro disfuction of the mononuclear phagocytic system.

Adrenocortical Function: A Clinical Comparison of Etomidat-Lipuro® and Hypnomidate®

Wiebalck A[*], Vanacker B, Van Aken H, Sermeus L, Bouillon R[**], Amery A[***]
Department of Anesthesiology, University Hospitals, Katholieke Universiteit Leuven, Belgium

Goal: The comparison of the two preparations of etomidate in terms of endocrinological changes after induction of anesthesia with Etomidat-Lipuro®, Hypnomidate® and Diprivan® as a control.

Materials and Methods: All 30 patients belonged to group 1 or 2 referring to the ASA classification and underwent minor surgery. They were allocated at random to one of the 3 induction agents. A radial artery catheter was inserted in every patient. Sampling took place 30 min before and 1 and 2 h after induction. Additional samples were drawn 30 min, 1, 2 and 22 hours after iv administration of 0,25 mg ACTH (Synacthen®, Ciba-Geigy). The plasma concentration of cortisol, 17a-OH-progesterone, aldosterone as well as the activity of renin was determined by HPLC (High Performance Liquid Chromatography).

Results and Discussion: Cortisol levels were depressed initially by all the hypnotic drugs used. While there was a spontaneous recuperation in the Diprivan® group after 2 hours combined with a positive overshooting response to ACTH stimulation, cortisol in the etomidate groups could not be stimulated. This phenomenon can be explained by the blockade of the 11-ß-hydroxylase (1). Cortisol normalized slowly during the following 24 hours. The 17a-OH-progesterone increase was significant in the etomidate groups after the administration of ACTH. The aldosterone level decreased after etomidate injection and did not normalize 24 hours later while there was a normal response to ACTH in the propofol group. There was a normal decrease of renin activity in the three groups after the administration of ACTH.

Conclusion: Cortisol and aldosterone are depressed by both etomidate preparations, but the clinical relevance is minimal in a normal patient after a single bolus injection (2).

ISOFLURANE INHIBITS Ca^{2+}-INDUCED INSULIN SECRETION FROM ELECTRICALLY PERMEABILISED ISLETS OF LANGERHANS

JP Desborough, PM Jones, SJ Persaud, SL Howell

Biomedical Sciences Division, King's College London,
Campden Hill Road, London W8 7AH, U.K.

Introduction: Isoflurane, like halothane and enflurane, inhibits glucose-induced insulin secretion from isolated rat pancreatic islets of Langerhans (1). Following metabolism of glucose inside islet B cells, generation of intracellular regulators, including Ca^{2+}, leads to activation of protein kinases and exocytosis of insulin. The mechanism by which volatile anaesthetics inhibit the stimulus-secretion pathway in pancreatic B cells has not been elucidated. We have studied the effects of isoflurane on insulin secretion from islets in which the cells have been permeabilised by high voltage discharge to allow the introduction of ions and small molecules into the intracellular compartment.

Methods: Islets were isolated by collagenase digestion of the pancreas and preincubated in a bicarbonate buffered medium at pH 7.4 for 30-60 min.The islets were washed in a permeation buffer with $CaCl_2$ added to produce a free Ca^{2+} concentration of 50 nM, and permeabilised by five exposures to an electric field of 3.4kV/cm (2). Reservoirs of buffer were equilibrated with O_2 (100%) or with O_2 and isoflurane 2%. Groups of five islets were then incubated at 37°C for 30 min in 0.5 ml permeation buffer containing 50nM- or 10μM-Ca^{2+}, with or without isoflurane. Insulin content in samples of buffer was measured by radioimmunoassay.

	Insulin secretion (mean ± SE) pg / islet / 30min n=9
Ca^{2+} 50 nM	98 ± 11
Ca^{2+} 50 nM + isoflurane	71 ± 5
Ca^{2+} 10 μM	150 ±15
Ca^{2+} 10 μM + isoflurane	95 ± 5

Discussion: Isoflurane inhibition of insulin secretion from permeabilised islets in the presence of a maximum stimulatory concentration of Ca^{2+} (10μM) suggests that isoflurane impairs the ability of the B cells to respond to Ca^{2+}. It is likely therefore that isoflurane acts at a stage in the secretory pathway beyond changes in intracellular Ca^{2+}.

EXERCISE AND MALIGNANT HYPERTHERMIA: FAMILY INVESTIGATIONS.

G KOZAK RIBBENS*, L RODET*,
J BORSARELLI***, M AUBERT** and PJ COZZONE*.
* CRMBM- URA CNRS 1186, Faculté de médecine, 13005-MARSEILLE; ** DAR, HIA LAVERAN, 13398-MARSEILLE ARMEES; *** DAR CHU, Hopital de la Timone, 13005 - MARSEILLE.

"Exercise Hyperthermia" (EH) is diagnosed when an exercising subject suffers concomitantly of mental confusion, hyperthermia above 40°5 C and rhabdomyolysis. A number of similarities have been observed between malignant and exercise hyperthermia symptoms and the pre-existence of a muscular disorder has been hypothetized in EH patients.

We have systemically investigated 60 patients with EH or exercise myolysis in the same way as patients with malignant hyperthermia (MH) syndrome, using non-invasive techniques (P31-NMR), contracture tests on biopsies according to the European Malignant Hyperpyrexia Group (EMHG) protocol (1) and morphological and biochemical examinations of the muscle fibers.

We report here the results of investigations which were conducted in the families of 3 EH patients, one of them died during the EH episode. According the EMHG classification, these 2 patients were found MH susceptible (MHS) with halothane and caffeine positive contracture tests. P31 NMR spectroscopy revealed an abnormal profile of muscular energetic metabolism, particularly when the exercise was conducted under partial ischemia with the application of a tourniquet.

Among the family members, MHS subjects were discovered. In some families, a link between MH and EH could be shown.

IS BURKITT'S LYMPHOMA AN ETIOLOGY OR A DIFFERENTIAL DIAGNOSIS OF MALIGNANT HYPERTHERMIA?

Lienhart A, Deriaz H, Desnault H, Masini JP, Delva E

Department of Anaesthesia and Intensive Care,
Saint Antoine Hospital, Paris, France

Association between Malignant Hyperthermia (MH) and Burkitt's lymphoma (BL) is occasionnally reported,[1,2] and generally considered as coincidental.[3,4] Nevertheless,the hypermetabolic crisis might not be MH.

Case 1: A 46 yr-old man was anaesthetized in 1986 with thiopental, pancuronium, ethrane and N_2O in O_2, for an exploratory laparotomy. A poor relaxation was noted, then a ventricular arrhythmia. A 9.2 mmol/l hyperkaliemia was associated with a severe acidosis (pH 6.90, $PaCO_2$ 81.5 mmHg) and a hyperpyrexia (39.5 °C). CPK remained within a normal range (69 IU). The patient died few hours later despite intensive cooling, alkalinization and dantrolene administration. A diagnosis of BL was made from tissue biopsy of a very large tumor.

Case 2: A 30 yr-old man was anaesthetized in 1992 with thiopental, atracurium, ethrane and N_2O in O_2, for an exploratory laparotomy. Within 15 min $P_{ET}CO_2$ increased from 44 to 57 mmHg. With dantrolene and a 20 l/min ventilation, $PaCO_2$ was 45 mmHg ($P_{ET}CO_2$ 42 mmHg), pH 7.10, bicarbonate 14 mmol/l, lactate 3.2 mmol/l, CPK 21 IU. Surgery was delayed and postanaesthetic hyperventilation was required to avoid hypercapnia. Two days later the laparotomy was performed and a very extensive tumor was discovered, of Burkitt's type. During and after surgery, the rectal temperature was 0.5 °C higher than the esophageal one. Postoperatively oxygen saturation was lower in the mixed venous blood than in the femoral vein. Dantrolene was discontinued; administration of corticosteroids and cyclophosphamide was followed by a rapid fall in temperature from 39.9 to 37 °C and a dramatic decrease in ventilatory requirement. Two weeks later a muscle biopsy was taken and *in vitro* contracture tests were performed: the phenotype was MHN. A second chemotherapy was induced, followed by an intense antitumor response. The patient died one month later, from septic complications of aplasia.

Discussion: More than 200,000 anaesthesia have been performed in our institution since 1984. We observed only these two cases of severe MH. A pure coincidence is very unlikely, since MH has been previously reported in association with BL,[1,2] not with other more common malignancies.[3] The normal *in vitro* contracture tests in one patient, and the normal CPK level in the two patients, suggest that the hypermetabolic crisis was not MH, but a severe disorder mimicing MH, related to the tumor itself. Corticosteroids and cyclophosphamide might be a more appropriate treatment than dantrolene alone.

INHIBITION OF INCREASE OF BLOOD THROMBOXANE CONCENTRATION BY ACETYLSALICYLIC ACID AFTER RELEASE OF TOURNIQUET IN LOWER EXTREMITY OPERATIONS

Raimo Ojanen, Seppo Kaukinen, Erkki Seppälä,
Liisa Kaukinen and Heikki Vapaatalo

Dept Anaesthesia, University Hospital and
Dept Biomedical Sciences, Tampere University,
Tampere, Finland

Background and goal of study: Ischaemia stimulates (TxA_2) synthesis. TxA_2 is a powerful aggregator of platelets and a vasoconstrictor. Tourniquet used in operations in extremities is a risk factor for thromboembolic complications. The metabolic products of arachidonic acid , e.g. TxA_2 may contribute to this. The inhibitor of TxA_2-synthesis given before placement of tourniquet probably would prevent the release of TxA_2 and harmful effects caused by it.

Material and methods: 32 generally healthy patients undergoing to orthopedic operations requiring tourniquet were studied. The patients were divided into four groups of eight patients. Three groups received acetylsalicylic acid (ASA) 25, 100, 500 mg p.o. three hours before operation in order to inhibit TxA_2 synthesis. The control group did not receive any drug for this purpose. The patients were anaesthetized using enflurane as a main anaesthetic agent. After induction of anaesthesia catheters were introduced into the radial artery and femoral vein in the extremity to be operated on. Blood samples for determination of serum and plasma TxB_2 concentrations were withdrawn simultaneously from artery and vein after the induction of anaesthesia and 3, 10, 30, 60 and 120 minutes after the release of tourniquet. Because TxA_2 disappears very fast, its metabolite TxB_2 was measured. It was determined using RIA.

Results and discussion: In the control group serum TxB_2 concentrations (S-TxB_2) increased distinctly after the release of tourniquet: 40.0 + 20.0 (SEM) - 73.5 + 39.0 ng/ml. The concentrations were at the highest at 60 minutes. In the patients received ASA 25 mg the base line of S-TxB_2 was lower than in the control group (17.0 +5.0 ng/ml), but this dose of ASA did not inhibit the increase of S-TxB_2 after release of tourniquet. The base line of S-TxB_2 in patients received ASA 100 mg was 1.9 + 0.6 ng/ml, and respectively in ASA 500 mg patients it was almost zero. Both these doses of ASA prevented the increase of S-TxB_2 after the release of tourniquet. Radial artery concentrations of S-TxB_2 behaved as venous concentrations.

Conclusions: 100 mg ASA p.o. is probably enough to prevent possible harmful effects caused by TxA_2 when tourniquet is used.

A.95

THE COMBINED PROPHYLACTIC ADMINISTRATION OF H1 AND H2 RECEPTOR BLOCKERS IN THE PREVENTION OF PROTAMINE RELATED HAEMODYNAMIC EFFECTS AND THE RELATION BETWEEN ANTIHISTAMINICS - LEUCOCYTES AND PULMONARY VASCULAR RESISTANCE

Durak P, Özgök A, Esen H, Erdemli Ö, Ebil S

Department of Anaesthesiology, Turkish High Advanced Hospital, Ankara, Turkey

Background and goal of study: We studied the combined prophylactic administration of H1 and H2 receptor blockers in the prevention of protamine-related haemodynamic effects.

Materials and methods: 30 patients subjected to coronary artery surgery were assigned to two groups. Patients in group I (n=15) received 50 mg Ranitidin-HCl iv after anaesthetic induction followed by 50 mg Chlorphenoxamin HCl into the cardiopulmonary bypass pump circuit during rewarming. The patients in group II (n=15) served as controls and had no treatment. The same format of anaesthesia was provided to all patients and consisted of fentanyl-diazepam-pancuronium. In both groups, the same amounts/kg of heparin and protamine sulphate were used for anticoagulation and reversal of heparin effects respectively. Systemic and pulmonary haemodynamics, haemogram and ionized serum-Ca were followed.

Results and discussion: In the control group, protamine induced significant decreases in systolic and mean arterial pressures (SAP $p<0.01$, MAP $p<0.05$) at 1 min and in diastolic arterial pressure ($p<0.05$) at 5 min. Ten min after protamine, serum leucocyte count was significantly decreased in the control group ($p<0.05$). There was also a significant negative correlation between pulmonary vascular resistance (PVR) and serum leucocyte count 5 min after protamine ($r=-0.85$). In group I, the administration of Ranitidine and Chlorphenoxamin prevented the haemodynamic changes observed in the control group whereas we did not observe any modification of the relationship between PVR and serum leucocyte counts.

A.96

THE RELATIONSHIP BETWEEN CARDIOPULMONARY BYPASS RELATED IMMUNOLOGIC EFFECTS AND COMPLEMENT, THROMBOXANE AND LEUCOCYTE PARAMETERS

Durak P, Özgök A, Saydam G, Türkmen A, Erdemli Ö, Ebil S

Department of Anaesthesiology, The Higher Specialization Hospital of Turkey, Ankar, Turkey

Backgound and goal of study: Our aim was to study immunological reactions related to cardiopulmonary bypass and protamine administration in patients undergoing coronary bypass surgery. For this purpose we followed plasma levels of complement ((C3), (C4) and (C5)), thromboxane B2 (TrxB2) and leucocyte counts.

Materials and methods: Twenty patients scheduled for coronary bypass surgery were subjected to general total intravenous anaesthesia with fentanyl-diazepam-pancuronium after morphine (10 mg) and diazepam (10 mg) premedication. Anticoagulation was provided with heparin, 4 mg/kg and all patients were reversed with the same amount/kg of protamine sulphate administered over 10 min via a central vein. Blood samples were taken along with haemodynamic measurements after anaesthetic induction and immediately before, and 10 min after protamine infusion, for measurements of TrxB2, (C3), (C4), (C5), arterial blood gases and total blood cell counts. Both arterial and central venous cell counts were obtained at each measurement period. Student´s T-test was used for the statistical analyses.

Results and discusssion: A significant increase of venous leucocyte count ($p<0.01$) which correlated with TrxB2 ($p<0.05$) was observed after protamine. In addition platelet count decreased significantly after protamine ($p<0.05$). (C3), (C4) and (C5) increased significantly ($p<0.01$ respectively) during cardiopulmonary bypass.

Conclusions: We conclude that leucocyte count and TrxB2 can be used to identify protamine-related reactions and that (C3), (C4) and (C5) could identify immunological reactions during cardiopulmonary bypass.

USE OF APROTININE DURING CYTOREDUCTIVE SURGERY OF OVARIAN CANCER

F. Lequeau, JL Bourgain, D. Castaigne, M. Samama

Department of Anesthesiology and Surgery, IGR, Villejuif and Department of Anesthesiology Hôpital Pitié Salpêtrière, Paris, France

Background : Cytoreductive surgery is often the first part of the treatment of ovarian cancer. This surgery is associated with major blood loss. The presence of Plasminogen activating factor has been reported in ovarian cancer cells. The aim of this study was to evaluate possible per-operative coagulation disorders in a control group and to test the efficacy of aprotinine infusion in the reduction of bleeding and correction of coagulation disorders during surgery.

Methods : Twenty one consecutive patients with ovarian cancer scheduled for cytoreductive surgery were included. The ten first patients being the control group, the following 11 patients received aprotinine 2 M.UK as a loading dose and 500 000 UK/hr up to 2 hours after surgery. Both groups received a standardized induction (etomidate 0.3 mg/kg, fentanyl 4 mcg/kg, vecuronium 0.1 mg/kg). Anaesthesia was maintained by isoflurane and intermittent injection of fentanyl and vecuronium. Coagulation tests were performed before and at the end of surgery. Blood loss was measured by the volume of aspirated blood and by weighing surgical swabs. In the post operative period, particular attention was given to the detection of phlebitis. In the case of respiratory symptoms, pulmonary angiography was performed to exclude pulmonary emboli. Results are expressed as mean (SD). Unpaired t-test was used for statistical analysis.

Results : As expected, ovarian surgery was associated with severe coagulation disorders. Although fibrinogen concentration and platelet count were significantly higher in aprotinine group, blood loss and blood replacement were similar in the two groups. Phlebitis was diagnosed in one case and no pulmonary emboli was detected in 5 patients with respiratory symptoms (aprotinine group).

Conclusion : Severe coagulation disorders are present during ovarian cytoreductive surgery ; a random study is necessary to confirm the beneficial effects of aprotinine.

BLOOD REQUIREMENTS REDUCTION IN ORTHOTOPIC LIVER TRANSPLANTATION WITH APROTININ.

Monedero P, Carrera J, Catalá J, Carrascosa F, Arroyo JL.

Anesthesiology Department. Clínica Universitaria. School of Medicine. University of Navarra. Pamplona. Spain.

Introduction: Hiperfibrinolysis seems to be an important cause of intra- and postoperative bleeding in patients undergoing orthotopic liver tranplantation (OLT). Aprotinin is an inhibitor of human plasmin and kallikrein that theoretically can inhibit the development of fibrinolysis. Aprotinin has proved to be useful in reducing operative bleeding in cardiac surgery (1) and there are good preliminary results in OLT (2). We have performed a retrospective study to evaluate the effect of aprotinin on hemostatic parameters and intraoperative requirements of blood derivates in 16 patients who underwent OLT. Results were compared with a historical group of 19 untreated patients.

Methods: Treated patients (n=16) received aprotinin as a bolus of 2 million kallikrein inactivator units (KIU) at induction, followed by a maintenance dose of 500000 KIU/h until the end of surgery. Standard clotting tests were performed and the total amount of blood derivatives infused intraoperatively was also measured.

Results: There were no significant differences between groups in preoperative diagnosis, Child-Pugh status and hemostatic variables.

In patients undergoing OLT, aprotinin significantly reduced ($p<0.05$) packed RBC (1620 ± 810 ml vs 4260 ± 3570 ml), fresh frozen plasma (2670 ± 870 ml vs 4710 ± 2130 ml), platelets (4.6 ± 5.5 units vs 10.3 ± 8.4 units), cryoprecipitates and albumin requirements as compared with untreated patients. Additionally, aprotinin reduced the usual increase in the D-dimer levels and the decreased alpha-2-antiplasmin during the anhepatic and postanhepatic periods, as compared to untreated patients.

Conclusions: We conclude that aprotinin is a highly effective treatment of intraoperative bleeding in patients undergoing OLT. Reduction of increased fibrinolysis seems to contribute to this effect.

HIGH DOSE APROTININ VERSUS DESMO-PRESSIN ACETATE TREATMENT IN CARDIAC SURGERY.

Hidalgo F, Páramo JA, Catalá JC, Carrascosa F, Monedero P.
Anesthesiology and Hematology Departments.
Clínica Universitaria. School of Medicine. University of Navarra. Pamplona. Spain.

Introduction

It has been suggested that platelet dysfunction and hyperfibrinolysis are a major cause of the hemostatic defect associated with cardiopulmonary bypass (CPB). Increased blood loss is the most obvious clinical manifestation reflecting this defect.

The aim of this study was to evaluate the influence of the administration of aprotinin and DDAVP in the prevention of bleeding after CPB.

Methods

This study included 124 patients, of which 110 accomplished the study, randomized into the following groups: Group A (n=28) treated with aprotinin 2×10^6 KIU immediately after anesthetic induction, 2×10^6 KIU in the extracorporeal circuit and 0.5×10^6 KIU/h until the end of surgery; group B (n=26) received DDAVP perfusion (0.3 µg/kg in 20 minutes) started after protamine neutralization; group C (n=28) were treated with DDAVP (0.3 µg/kg) as in group B and an additional dose 6 hours after surgery; and group D (n=28) wich not receive any treatment.

Postoperative blood loss and blood requirement was measured. Some fibrinolysis parameters and other coagulation parameters were studied before, during and after surgery.

Results

There was a significant reduction in postoperative bleeding and blood requirements in group A as compared to groups B, C and D (table I). Whereas no differences in the analyzed parameters were observed in both DDAVP treated groups with respect to the untreated group, we found a significant reduction of a2-antiplasmin consumption (p<0.02) and of fibrin degradation products generation (p<0.001) in the aprotinin group.

Conclusions

We conclude that aprotinin offers a better alternative than DDAVP in the prevention of bleeding after CPB surgery and this effect is clearly related to a reduction of fibrinolysis.

Aprotinin does not decrease surgical bleeding and could promote arterial thrombosis in the pig: A prospective randomized, blind, study.

ChM. Samama[1], E. Mazoyer[2], P Bruneval[3], Ph. Bonnin[4], M. Bonneau[5], G. Pignaud[2], P. Viars[1], JP. Caen[2], LO.Drouet.[2]
1: Département d'Anesthésie, Hopital Pitié, Paris -2: INSERM U 353, IVS, Paris -3: Département d'Anatomo-Pathologie, Hopital Broussais, Paris -4: Laboratoire d'Explorations fonctionnelles, Hopital Lariboisière, Paris -5: INRA, Jouy, France

Hemostatic properties of aprotinin could be counterbalanced by an increased risk of thrombosis. A randomized, blind study was conducted to consider the potential thrombogenicity of aprotinin, using the Folts' model on femoral arteries in 12 pigs. The flow variations were measured by a pulsed Doppler in anesthetized animals. The spleen was exposed and the very distal extremity was injured for splenic bleeding. Ear immersion bleeding time was performed. During the first part of the study, a stenosis was performed succcessively on both femoral arteries, each for a period of 30 min, without prior injury, to assess the integrity of the vessel, and to check that the arteries did not develop spontaneous cyclic flow reductions (CFR), permanent cessation of flow (PCF) or partial thrombosis, when a stenosis is applied. Then the clamp was released and a bolus of placebo (saline), or aprotinin (4 millions KIU, followed by a continuous infusion of 1 million KIU.hr^{-1}), was administered. At the end of the bolus, the second part of the study began. Stenosis was applied to the arteries. If CRF, PCF, or partial thrombosis were observed, without prior injury, then the infused drug (aprotinin or saline) was considered a prothrombotic drug, and the opposite artery was studied. For each animal, right and left femoral artery segments were fixed and studied (morphologic study). Eighteen arteries were studied. In the aprotinin group, 6 arteries out of 8 developped an unexpected spontaneous thrombosis, as compared with only 2 out of 10 arteries in the control group (p=0,02). The morphologic study confirmed the occcurence of thrombosis in 4 normal arteries out of 7 studied, as compared with only 1 out of 8 in the control group. The splenic bleeding time and the ear immersion bleeding time were not different from one group to another. No difference could be evidenced with regard to the values of activated partial thromboplastin time, prothrombin time and fibrinogen. Aprotinin did not reduce the surgical bleeding but it could promote the developpement of arterial thrombosis in the pig.

A.101

EFFECTS OF RECOMBINANT-HUMAN ERYTHROPOIETIN ON POSTOPERATIVE TRANSFUSION REQUIREMENTS IN SUBJECTS UNDERGOING MAJOR ORTHOPAEDIC SURGERY.

Per P Faris, M Ritter, R Abels, D Gordon, r-HuEPO Surgery Study Group.

From the Center for Hip & Knee Surgery, Mooresville, Indiana, USA.

Background & goal of study: This study was undertaken to evaluate the effect of pre- and postoperative recombinant-human erythropoietin (r-HuEPO) on the amount of homologous blood exposure in the perioperative period, the hematologic effects of r-HuEPO on subjects in the perioperative period, and the general well-being of subjects before and after major orthopaedic procedures.

Materials & methods: 200 subjects were enrolled in a multicenter, randomized, double-blind, placebo-controlled study and divided into 3 groups: r-HuEPO 300 and 100 U/kg/day and placebo. A total of 15 doses were given s.q. beginning 10 days pre-op and extending to the 4th postop. day. Subjects were informed of the investigative nature of the study, maintained on oral iron supplements, and did not preoperatively donate autologous blood. Laboratory analysis included hemoglobin, hematocrit, reticulocyte counts and EPO antibody testing. Reports of adverse events, incidence of homologous transfusions, and energy assessments performed on an analog scale were also recorded. Decision to transfuse was physician dependent.

Results & discussion: 185 of the 200 originally enrolled subjects received ≥ 14 doses, making them evaluable for efficacy. Discontinuations were predominantly due to adverse events, none of which resulted in sequelae. There was not statistically significant differences between the groups in subject completion, sex, age, ethnic origin, surgical procedure, diagnosis, any preoperative laboratory data, or number of subjects excluded from efficacy evaluation. Prestudy to presurgery changes in hematocrit were from 38.8 to 41.2% (r-HuEPO 300, $p<0.002$)) from 39.6 to 41.4% (f-HuEPO 100, $p<0.002$), and from 38.9 to 37.3% (placebo, n.s., $p=0.001$ comp. to r-HuEPO groups). In addition, during this period, reticulocyte counts changed from 1.6 to 5.4% (r-HuEPO 300, $p=0.001$), from 1.5 to 4.6% (r-HuEPO 100, $p=0.001$), and from 1.6 to 1.7% (placebo, n.s., $p=0.001$ comp. to r-HuEPO groups). Homologous transfusion was required by 16.7% (r-HuEPO 300), 25.0% (r-HuEPO 100), and 53.7% (placebo, $p<0.001$ comp. to r-HuEPO groups) of subjects. No differences in energy assessments were identified between groups and there was no new development of anti-EPO antibodies during the study.

Conclusions: r-HuEPO successfully reduced the need for homologous transfusions in the perioperative period in subjects undergoing major orthopaedic surgery. None of the adverse experiences were significantly more prevalent among r-HuEPO-treated than among placebo-treated subjects and reported events exhibited no clinical significance in this study. Presurgery hemtocrits and reticulocyte counts significantly increased, with a resultant perioperative decrease in the need for homologous transfusions in the r-HuEPO groups compared to placebo.

A.102

PEROPERATIVE AUTOTRANSFUSION IN EMERGENCY SURGERY FOR SPINE TRAUMA.

Bruno Riou, Silvana Cavallieri,
Raymond Roy-Camille, Pierre Viars.
Departments of Anesthesiology, and Orthopedic and
Trauma Surgery, CHU Pitié-Salpêtrière, Paris,
France.

Background and goal of the study: Emergency surgery for spine trauma induces significant blood loss, requiring blood transfusion. Peroperative blood salvage is often the only technique which could be applied during emergency surgery for spine trauma, but it has never been assessed during this condition. Thus, we assessed the efficacy of peroperative autotransfusion during emergency surgery for spine trauma.

Patients and methods: We retrospectively analyzed 230 consecutives cases of emergency surgery for spine trauma (1989-92) admitted to a single level 1 Trauma Center. Patients who required perioperative (<24 hrs) blood transfusion were included and divided into 2 groups : those who benefited from intraoperative autotransfusion (Cell-Saver^R, Haemonetics) and those who did not (Control). Anesthesia was usually induced with thiopental and maintained with nitrous oxide, isoflurane, and fentanyl, and muscle relaxation achieved with vecuronium, . Surgery was performed in the prone position and included reduction, laminectomy, and fixation using plates and pedicle screws. Data are mean ± SD.

Results: Among the 230 patients, 109 required blood transfusion : 65 were control and 44 were in the Cell-Saver group. There were no significant differences between the 2 groups for sex ratio, incidence of spinal cord injury (62 %), incidence of dorsolumbar (72 %) versus cervical injury, and Injury Severity Score (24 ± 12), but significant differences in age (40 ± 18 vs 32 ± 13), duration of surgery (211 ± 93 vs 267 ± 87 min), crystalloïd (2223 ± 968 vs 2669 ± 1186 ml) and colloid (1669 ± 1238 vs 2159 ± 1238 ml) administration were noted between Control and Cell-Saver Groups, respectively. In the Cell-Saver Group, homologous blood transfusion was significantly reduced (538 ± 952 vs 1173 ± 1183 ml, $p<0.005$) as well as the number of patients who received homologous blood (45 vs 81 %, $p<0{,}001$).

Conclusion: Peroperative autotranfusion using the Cell-Saver technique enabled a significant reduction in homologous blood transfusion in emergency surgery for spine trauma.

A.103

EFFECTS OF POSTOPERATIVE AUTO-TRANSFUSION IN SPINE SURGERY

Bruno Riou, Marco Guerrero, Michel Arock, Mauricio Ramos, Pierre Viars

Departments of Anesthesiology and of Emergency Biology, Groupe Hospitalier Pitié-Salpétrière, Université Paris VI, Paris, France

Background and goal of the study: In orthopedic surgery, postoperative bleeding may be important. Although the efficacy of postoperative autotransfusion of shed blood in orthopedic surgery has been recently demonstrated, there is still limited data on its biological effects. The goal of our study was to assess these effects after spine surgery.

Patients and methods: After ethical approval and written informed consent had been obtained, 50 patients undergoing spinal surgery were randomly allocated to Control (n=25) and Solco (n=25) groups. Both groups had their postoperatively (5 hrs) drained blood collected (Solcotrans Orthopedic Plus^{R}) but only the Solco group underwent reinfusion if volume was > 200 ml. Venous blood was withdrawn preoperatively, and 5, 8 and 24 hours postoperatively, and 15 min following reinfusion. Drainage blood was also withdrawn. The following parameters were measured : hematocrit (Ht), platelet count (P), partial activated thromboplastin time (APTT), prothrombin time (PT), fibrinogen (F), and plasma potassium (K^+), free plasma hemoglobin (fHb) and D-dimers concentrations. Aerobic and anaerobic blood cultures were performed. Data are mean ± SD.

Results: The shed blood had elevated level of D-dimers, did not clot, was sterile and showed : Ht : 0.26± 0.11 ; P : 80 ± 63 $G.l^{-1}$; F < 0.1 $g.l^{-1}$. The volume collected was > 200 ml in 21 patients in the Solco group who were autotransfused (382 ± 101 ml, range 200-600 ml), and in 16 patients in the Control group. Within 15 min following reinfusion there was a moderate decrease in P (181 ± 74 vs 224 ± 90 $G.l^{-1}$, $p<0.001$), and F (2.1 ± 0.8 vs 2.3 ± 0.9 $g.l^{-1}$, $p<0.02$), and an increase in circulating D-dimers ($p<0.001$) without modifications of PT, APTT, Ht, fHb and K^+. Blood cultures were sterile. No side-effects were observed. There were no significant differences in any biological parameters between the two groups at the 8th (and 24 th postoperative hours.

Conclusion: Postoperative autotransfusion is a simple technique with few side-effects. It can be safely associated with other methods used to decrease homologous blood transfusion requirements.

A.104

ACUTE PREOPERATIVE PLASMAPHERESIS DURING CARDIAC SURGERY

G Armellin, D Pittarello, D Penzo, GP Giron

Department of Anaesthesiology, Padua University, Italy

Background and goal of study: In the last few years much attention has been focused on preoperative autologous deposit of blood. In cardiac surgery, this technique is not always feasible. To reduce the use of homologous plasma and platelets in cardiac surgery we have begun a program of harvesting autologous platelet-rich plasma (PRP) from patients prior to cardiopulmonary bypass (CPB).

Materials and methods: 40 consecutive patients scheduled for major cardiac surgery were randomly assigned to two groups; (1) acute plasmapheresis (APP) harvesting autologous PRP; (2) control group. APP was started after induction of anaesthesia. Twenty percent of the estimated plasma volume was removed and replaced with colloids. APP was performed by means of the Haemonetics Plasma Collection System Untralite. This method involves removal of blood into a centrifuge to separate it into PRP and red cells. Using a single needle technique blood was collected from the internal jugular vein while an anticoagulant was immediately added. After plasma separation was completed, the red cells were retransfused through the same needle. The PRP was retransfused at the end of CPB after heparin reversal. The following parameters were measured: haemoglobin, haematocrit, number of platelets, white and red blood cells, osmolarity, amount of total proteins, fibrinogen level, prothrombin time, partial thromboplastin time and electrolytes. Blood samples were taken before operation, at the arrival in the ICU, and 24 and 48 h later. Blood loss from the chest tube drainages and use of homologous blood products were recorded.

Results and discussion: The two groups were comparable with regard to demographic data, type of operation, duration of anaesthesia, CPB and ischaemia time. There were no differences between measured laboratory parameters in the two groups. In contrast average plasma usage and albumin usage were lower in the APP group (0.94 vs 2.39 units, $p<0.05$ and 2.18 vs 4.40 units, $p<0.05$ respectively). Our study was initiated to determine the effects of autologous PRP collected immediately before CPB upon homologous plasma and platelet usage. It demonstrates that APP resulted in significant savings of albumin and plasma.

Conclusion: We can affirm that APP is easy to perform, safe and economic. It might be another step to minimize patients' exposure to homologous blood products. APP can be performed even in patients with low haemoglobin in whom acute normovolaemic haemodilution is contraindicated. Further studies with larger patient materials are needed to finally establish the role of this technique in cardiac surgery.

A.105

TRANSCRANIAL DOPPLER SONOGRAPHY: EFFECT OF PROPOFOL AND THIOPENTAL IN PATIENTS WITH BRAIN TUMORS AND BRAIN INJURIES

Werner Schregel, Christoph Geißler, Udo Bredenkötter, Heinrich Schäfermeyer

Department of Anaesthesia and Intensive Care Medicine, Ruhr-Universität Bochum (RUB), Bochum, FRG

Background and goal of study: Transcranial Doppler sonography (TCD) permits noninvasive measurement of the flow velocities (v) in the middle cerebral artery (MCA). Assuming unaltered cross-sectional vessel area (VA) of the MCA, alterations of v indicate altered cerebral blood flow (CBF). The effect of anaesthetic agents on the human MCA has not been clearly determined due to ethical and methodological problems. Aaslid has pointed out, that backscattered Doppler-power is proportional to transcranial "VA" (1) of the MCA.
Material and methods: After approval of the ethical committee (RUB) six groups of 12-15 patients with brain tumors, brain injuries or without cerebral lesions were investigated if Propofol (P) or Thiopental (T) were indicated for anaesthesia or sedation. The TCD-probe was directed to the MCA (45 mm). v and "VA" were analyzed with the TCD-device 2000 S (EME) before and after 1-2,5 mg/kg P or 2-5 mg/kg T.
Results and discussion: P or T did not influence "VA". The observed reductions of v are likely to reflect real CBF-reductions induced by T or P. v decreased by 44 % (P) respectively 27 % when T was administered in patients without cerebral lesions; the reactivity to P or T was reduced or absent in some patients with brain injuries or brain tumors. Similar results (^{133}Xe) predicting an unfavourable outcome were reported by Cold (2).
Conclusion: P and T exert their vasoconstrictive effects on cerebral arterioles. TCD seems useful to monitor CBF-reductions induced by P or T. TCD-determined P- or T-reactivity may thus become a prognostic method in neurosurgical patients.

A.106

JUGULAR BULB METABOLIC MONITORING DURING HYPERVENTILATION IN SEVERE HEAD TRAUMA PATIENTS

Cathy De Deyne, Tom Vandekerckhove, Johan Decruyedaere, Jan Poelaert, Francis Colardyn

Department of Intensive Care, Universital Hospital, Ghent, Belgium

Background and goal of study: In the present study, we analyzed the possibly ischaemic events during hyperventilation of patients with severe head trauma by monitoring jugular bulb metabolic data.

Materials and methods: Twenty patients suffering from severe head injury (GCS<8) were selected. They all had intracranial hypertension with an ICP above 20 mm Hg as measued by an intraventricular catheter despite optimal management incuding sedation, normoventilation, CSF drainage and iv mannitol. The patients were hyperventilated over 6 h, decreasing paCO2 from a mean of 34 mm Hg to a mean of 25 mm Hg. During this period, we continuously monitored jugular bulb oxygen saturation (SjO2) by the oximetry technique. In addition, we sampled blood for determination of the jugulo-arterial lactate concentration difference (jADL) before and at the end of the 6 h period.

Results and discussion: Eleven patients showed a significant decrease (e.g. > 5% units) of SjO2 during hyperventilation, eight of whom also had a significant increase of jADL (e.g. > 1.0 mg/dl). Six of these eleven patients had a lactate/oxygen index (jADL/AVjDO2 > 0.4 mg/dl/Vol%), strongly suggesting the development of brain oedema during hyperventilation. Despite 12/20 patients demonstrating decreasing ICP after institution of hyperventilation, six of the 12 had jugular bulb metabolic indices of brain ischaemia with this therapy.

Conclusions: These results again confirm the idea that "blind" hyperventilation could do more harm than good. However, hyperventilation remains an effective therapy against intracranial hypertension, provided jugular bulb metabolic data are used to guide safe hyperventilation.

A.107

SUFENTANIL INCREASES INTRACRANIAL PRESSURE IN PATIENTS WITH HEAD TRAUMA

Jacques Albanese, Xavier Viviand, Olivier Durbec,
Bernard Alliez, Claude Martin

DAR Hôpital Nord - 13326 Marseille - Cedex 15
France

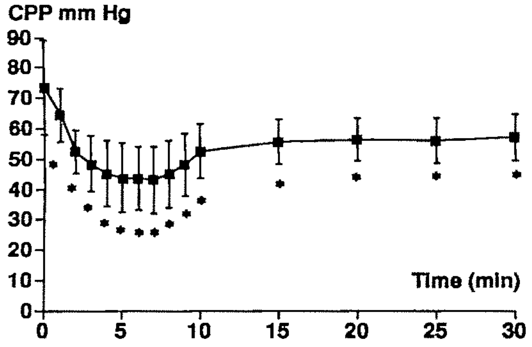
Background and goal of study : several recent studies in both animals and humans have suggested that sufentanil may be associated with significant increases in cerebral blood flow (CBF) and/or intracranial pressure (ICP) (1,2). The safety of using these agents in neurosurgical patients is thus controversial.

Materials and methods : the subjects were 10 mechanically ventilated head injured patients (with informed consent from family and approval by the Research Commitee of our institution). After obtaining control of ICP (between 15 and 25 mmHg) hemodynamic values and blood gas tension (PaCO2 between 30 and 35 mmHg) with propofol infusion and mechanical ventilation, the level of sedation was deepened with an IV bolus injection of sufentanil (1mg/kg/6min) followed by an infusion of 0.005 mg/kg/min. Mean arterial pressure (MAP), ICP (fiberoptic intracranial pressure monitor) and end-tidal CO2 were continuously measured and recorded at 1 minute intervals throughout the 30 minute study period. The cerebral perfusion pressure (CPP) was calculated by subtracting ICP from MAP.

Results and discussion : sufentanil produced a significant increase in ICP (70% increase) which peaked at 5 min, then gradually decreased and return to baseline after 15 min (Fig1). This was accompanied by a significant decrease in MAP (19.5% decrease) and thus in CPP (37% decrease) (figure). After 5 min, MAP and CPP gradually increased but remained signicantly decreased throughout the study.

Conclusion : this study shows that in the presence of decreased intracranial compliance, the increase in CBF produced by bolus injection of sufentanil was accompanied by an important increase in ICP which can result in a risk of cerebral ischemia, since CPP decreased dramaticaly below 45 mm Hg. During sufentanil infusion which followed the bollus, ICP returned to baseline, and CPP remained greater than 55 mm Hg.

References : 1Anesthesiology 69: A627, 1988. 2 Anesth Analg 68: S196,1989



Mean ± SD CPP over time after IV bolus of sufentanil. Values were plotted at 1 min intervals after drug administration during the first 10 min. * $p < 0.05$ compared to baseline value using Dunnett's test

CARDIAC FUNCTION IN ANEURYSMAL SUBARACHNOID HAEMORRHAGE

Nadia Moulay, Véronique Mahé, Adrien Descorps-Déclère,
Claudine Cosson, Claude Ecoffey.

Département d'Anesthésie - Réanimation, Université Paris-Sud, Hôpital de Bicêtre, 94275 - Le Kremlin-Bicêtre,
FRANCE

Background and goal of study: Electrocardiographic (ECG) changes occur frequently after subarachnoid haemorrhage (SAH) (1). The aim of this study was to investigate the significance of ECG changes by echocardiographic assessment of cardiac function and by serum creatine kinase dosage.

Material and methods: Between May 92 and October 92, we studied prospectively, all the patients with SAH documented by computed tomography scanning and cerebral angiography and admitted to the hospital the first day after the bleeding. We recorded age and neurological status (Hunt and Hess' score). ECG were performed twice daily for the first 3 days after the admission, they were considered abnormal if the T wave was inverted or flattened, the S-T segment was elevated or depressed or a pathological Q wave was present. echocardiography (echo) was performed initially before the third day and after 10 days if the first exam showed abnormalities: hypo-, a- or dyskinesia. Creatine kinase, i.e. total and isoenzyme MB (CK-MB) was dosed by immunoenzymometric assay and a calculated ratio > 1.5 was considered pathological.

Results and discussion: The individual values were summarized in the table:

patients	age yrs	G	T	S-T	Q	CK-MB	echo < day 3	E
1	42	1		X			N	
2	28	2				-	N	
3	69	2	X	X		-	N	
4	45	2	X	X		X	A N	S
5	54	2				-	N	
6	41	2	X			-	N	S
7	33	4	X	X		X	N	S
8	72	2	X			-	N	
9	66	3		X	X	X	N	S
10	40	3	X		X	X	N	
11	24	2					N	
12	68	4			X		N	D
13	38	4	X				A N	D
14	39	1				-	N	
15	25	1	X			-	A N	
16	29	2				-	N	
17	60	3				-	N	
18	69	3		X		X	A N	D
19	46	2				-	N	
20	48	4				-	N	

G: Hunt and Hess grade; T: abnormality of the T wave, S-T: change of the S-T segment, Q: pathological Q wave presence; E: evolution, S: intracranial arterial spasm; D: death.

As previously reported, we found a relationship between the increase in the CK-MB and the incidence of ECG changes (2) and the severity of neurologic state (3). Nonetheless, there was no close relationship with the abnormalities of the myocardial wall motion; these changes were transient (patients 4 and 15 had an echo normal at day 10, patients 13 and 18 were died within 10 days). In addition, patient 4 had a clinical pulmonary oedema which was resolved rapidly with diuretic therapy.

Conclusion: In spite of the absence of a close relationship between the ECG changes and the abnormalities of Echo we recommend to perform an echocardiographic assessment of cardiac function in aneurysmal subarachnoid haemorrhage.

References: 1) Harries AD: Postgraduate Med J 1981; 57: 294-296, 2) Pollck C et al: J Am Coll Cardiol 1988; 12: 600-605, 3) Fabinyi G et al: J Neurol Neurosurg Psych 1977; 40: 818-820

A.109

EXTERNAL VENTRICULAR CSF DRAINS INFECTIONS

Véronique Mahé, Nathalie Kermarrec, Claude Ecoffey

Département d'Anesthésie - Réanimation, Université Paris-Sud, Hôpital de Bicêtre, 94275 - Le Kremlin-Bicêtre, FRANCE

Background and goal of the study : The main complication of external ventricular CSF drains (EVD) was infections. We performed a retrospective study to assess the relationships among EVD duration, systemically administered antibiotics and CSF infections.

Material and methods : 63 EVD inserted from January 90 to December 91 in 54 neurosurgical patients ,whose age ranged from 7 to 76 years and IGS from 1 to 20, were analyzed in this study. CSF withdrawn from the drain was collected daily for laboratory bacteriological, biochemical and cytological analysis and microbiological culture, until the EVD removal. The daily glycemia and administered antibiotics (AB), the EVD duration, the day a colonization and/or an infection occurred were recorded. A CSF colonization was defined by a positive direct examination or a positive culture of CSF without biochemical and cytological abnormalities. The diagnosis of CSF drain infection was established by a low glucose value or leucocytosis without a blood contamination, however the bacteriological analysis results were affected by the previous antibiotic treatment.

Results and discussion : Underlying neurosurgical pathologies, age, IGS, CGS and the delay between the hospital admission and the day of drain insertion were the same in both groups. The other results (mean ± SD) were as follows:

EVD	n	D (day)	d (day)	AB (appropriate)
without infection	25	8 ± 4		16
colonization	27	16 ± 12*	5±4	16(10)
infection &	22&	18 ± 13*	10±9	15(10)

& 12 EVD with colonization before infection; * p < 0,01 vs without infection, D: EVD duration, d: delay between insertion and colonization or infection, appropriate AB: isolated pathogens were susceptible to previous AB.

EVD	n	SC	SA	Others	Meningitis
colonization	27	13	5	9	
Infection	22	6	5	5	6

S C : coagulase negative staphylococci, S A : staphylococcus aureus.

For 6 patients, AB was effective to treat a meningitis: there was leucocytosis with low glucose value but microbiological culture remained negative.

Conclusion : There was a significant association between infection and colonization rates and the duration of EDV but the systemic antibiotics therapy has no effect. Probably local administration of antibiotics should be more efficient for treatment of EDV infection.

EEG-MONITORING DURING DEFIBRILLATOR-IMPLANTATION: EFFECTS OF REPETITIVE CEREBRAL ISCHEMIA ON ELECTRIC BRAIN ACTIVITY

[*]C.Spies, [$]S.Kraemer, [*]T.Heil, [*]T.Neumann, [*]K.Reinhart

[*]Department of Anaesthesia and Intensive Care Medicine,
[$]Department of Neurology, Steglitz Medical Center,
Free University Berlin, Berlin, Germany

Background and goal of study: Implantation of an internal automatic cardioverter defibrillator (ICD) is a therapeutic regimen for malignant tachyarrhythmias.[1] To assess the individual defibrillation threshold repetitive induction of ventricular fibrillation is required. During each testing cardiac arrest and, hence, intermittent interruption of cerebral perfusion occurs, which can be registered by EEG-monitoring of electric brain activity.[2] There are hints that repetitive interruption of cerebral perfusion is associated with a decreased ischemic tolerance.[3] We investigated whether time course and number of intraoperative testing influenced duration and reversibility of EEG changes.

Material and methods: In 15 male patients, aged 59 +/- 5 years, extended perioperative monitoring (pulmonary and radial artery catheter, pulse oximetry, capnography, temporary pacemaker) and balanced anesthesia were performed. Conventional six channel EEG (lead position at the International 10-20-System: FP1-C3, FP2-C4, C3-O1, C4-O2, F7-T5, F8-T6) was continuously recorded. The curves were evaluated visually. Statistical analysis was performed by the Wilcoxon rank-sum test.

Results and discussion: Duration of EEG changes significantly increased with the number of testings (p=0.001, fig.1) and with the duration of cardiac arrests (p=0.037). Shorter intervals between testings also significantly increased the duration of EEG changes (p=0.001). EEG changes outlasting operation were found after the fourth testing in individual patients and were observed more frequent with increased numbers of testings (p=0.003).

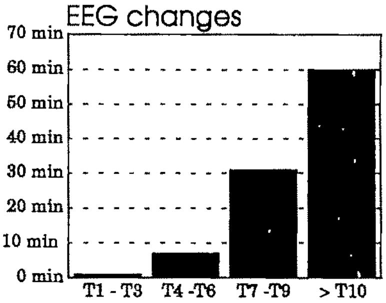

Fig.1: Number of testings

Conclusion: Intraoperative EEG-monitoring can detect cerebral hypoperfusion. Before induction of further testings restitution of electric brain activity can be evaluated by intraoperative EEG-monitoring.

A.111

MIDAZOLAM PREVENTS KETAMINE-INDUCED STIMULATION OF CEREBRAL METABOLISM

Jonas Åkeson, Sven Björkman, Kenneth Messeter

Departments of Anaesthesia and Intensive Care, and
Experimental Research, Lund University,
Malmö General Hospital, and Hospital Pharmacy,
Malmö General Hospital, Malmö, Sweden

Background and goal of study: An anaesthetic dose of ketamine induces a biphasic metabolic response of the brain including a delayed increase in the cerebral metabolic rate for oxygen ($CMRO_2$) and a sustained decrease in cerebral blood flow (CBF) *[1]*. Midazolam has been reported to attenuate clinical symptoms of excitation during ketamine anaesthesia. We have thus studied the cerebral haemodynamic and metabolic responses to ketamine in combinations with low doses of midazolam.

Materials and methods: Cerebral variables were assessed on five occasions during an 80 min period following rapid infusion of ketamine (10.0 $mg \cdot kg^{-1}$) and midazolam (0.10 or 0.25 $mg \cdot kg^{-1}$) in twelve normoventilated pigs anaesthetized with fentanyl, nitrous oxide and pancuronium *[2]*. CBF was calculated from the initial slope of the cerebral clearance curve of ^{133}Xe injected into the internal carotid artery and recorded by an extracranial scintillation detector.

Results and discussion: Both drug combinations augmented the haemodynamic depression and prevented metabolic stimulation of the brain as compared with ketamine alone. A 45% decrease in CBF ($P<0.001$) induced by the 0.25/10 midazolam/ketamine regimen was found to be associated with a 40% increase in CVR ($P<0.05$). Systemic blood pressure was similarly influenced by ketamine-midazolam and ketamine.

Conclusions: A ketamine-midazolam combination comprising 1-2.5% midazolam is superior to ketamine alone for anaesthetic use. Compensatory pharmacodynamic effects on $CMRO_2$ are probably involved in the attenuation by midazolam of excitatory cerebral symptoms associated with ketamine anaesthesia.

NITROUS OXIDE INDUCED NEURONAL DEPRESSION: MODIFICATION THROUGH BENZODIAZEPINE RECEPTORS

M. Dzoljic, E. Geller, J. Rupreht, W. Erdmann
M.R. Dzoljic
Department of Anaesthesiology, Faculty of Medicine
Erasmus University, Rotterdam, The Netherlands

Background and goal of study: The high correlation between the lipophilicity and the potency of anaesthetic agents has been interpreted as evidence that general anaesthesia occurs secondary to a non-specific disruption of neuronal cell membranes lipids. The extent to which the above hypothesis is accurate is questionable and the mechanism(s) through which such drugs produce unconsciousness, amnesia and analgesia remains unclear. Recent studies suggest more specific interaction through membrane proteins. The purpose of this study was to determine the extent of nitrous oxide (N_2O)-induced neuronal depression, by measuring the visual evoked potentials (VEP) after exposure to Ro 15-4513. This partial inverse agonist was chosen because of its specific interaction with ethanol induced depression, which is able to accomplish cross-tolerance with N_2O (1).

Materials and methods: VEP were recorded in 20 free moving Wistar rats before and during exposure to 70 % N_2O in oxygen (O_2). After 1 hr of exposure to N_2O, Ro 15-4513 (10 mg/kg) or the solvent Tween (0.3%), i.p. was given. An other group of 10 rats were given Ro 15-4513, (10 mg/kg) i.p. while breathing air to ensure the drug doesn't have an epileptogenic property given at this concentration. With 15 min intervals three VEP recordings were made and the peak latencies as well as the peak-to-peak amplitudes were determined.

Results and discussion: While breathing 70 % N_2O in O_2 there were no significant changes in latencies of the first 6 peaks, although the longer latencies showed a tendency towards an increase. All first 5 peak-to-peak amplitudes showed a significant depression during exposure to N_2O, which was partially but significantly reversed by Ro15-4513 but not by the solvent Tween. Ro15-4513 given to rats while breathing air did not increase the amplitudes suggesting its effects were not aspecific but related to a change induced by N_2O.

Conclusion: We conclude that depression as induced by N_2O can partially be reversed by Ro15-4513, a benzodiazepine inverse agonist. This partial reversal of N_2O anaesthesia indicates that central depression might be due to an interaction between N_2O and a binding site of GABA-A complex directly or through pertuberation of the membrane surrounding the macromolecule.

Dexmedetomidine does not exercise its anesthetic action through GABA.

Markku Salonen, Joan Kendig, Billy O'Connor, Mervyn Maze.
Department of Anesthesia, Stanford University, Stanford CA & Turku University, Turku, Finland

In our earlier studies, we have demonstrated a significant sedative synergistic interaction between midazolam and dexmedetomidine in rats (Salonen et al 1991). Midazolam, similarly to many other anesthetic agents, is considered to cause its main action through potentiating GABA's actions. In this series of studies we wanted to seek the possible involvement of GABA-ergic components in the synergy found between dexmedetomidine and midazolam.

The following possibilities were examined:

1) **Presynaptic**: Dexmedetomidines effects on *GABA-release* in the neonatal rat spinal cord model. 20 nM Dexmedetomidine was applied onto spinal cords bathing in the artificial CFS. 100 nM rauwolscine was used as an antagonist, and high potassium as a positive control. The GABA concentrations were determined by HPLC.

2) **Post synaptic**: Effect of bicuculline on the inhibiting effect of dexmedetomidine on the neonatal rat *ventral root potential.* Dexmedetomidine's effect on the neonatal rat spinal cord *dorsal root potential*, which is a GABA$_A$-receptor mediated electro-physiologic response.

3) **Post synaptic**: Dexmedetomidine's effects on the GABA-stimulated *chloride-flux* in rat cortical synaptosomes. Chloride flux was assayed in the presence and absence of midazolam. The effect of GABA induced desensitization on the chloride flux was also measured.

RESULTS: Bicuculline was capable of blocking dexmedetomidine's inhibiting effect on the ventral root potential. The dorsal root potential was not affected by dexmedetomidine. No effect was seen in GABA-release or GABA-stimulated chloride flux.

CONCLUSION: Dexmedetomidine seems to represent a particular category within anesthetic agents, not involving GABA-ergic transmission. We conclude that GABA is not involved in the synergistic interaction between alpha$_2$ agonists and benzodiazepines.

DIFFERENTIAL EFFECTS OF SPECIFIC DELTA AND KAPPA OPIOID ANTAGONISTS ON THE BIDIRECTIONNAL EFFECT OF NALOXONE IN ARTHRITIC RATS.

I.Cattaneo, V.Kayser, G.Guilbaud

Unité de Recherches de Physiopharmacologie du Système Nerveux, INSERM U 161, Paris, France

Background and goal of the study: Previous behavioural studies have shown that naloxone (Nx) induces bidirectionnal effects in arthritic rats (1). The goal of this study was to determine the opioid receptor classes underlying these two effects, using δ and κ antagonists.
Materials and methods: We used 220 male Sprague-Dawley rats rendered arthritic by the inoculation of Freund's adjuvant. As a nociceptive test we used the measure of the vocalization thresholds to paw pressure. Firstly we determined the doses of the δ-antagonists (ICI-174,864 and naltrindole) and of the κ–antagonist (MR2266) without analgesic or hyperalgesic action per se (respectively 10mg/kg, 1mg/kg and 0.2mg/kg iv). Secondly, we confirmed the specificity of each antagonist, on the antinociceptive effect of specific agonists (δ-agonist DTLET, κ–agonist U69593, μ-agonist DAMGO and morphine). Thirdly, we observed the action of these two antagonists on the paradoxical analgesia produced by 3μg/kg iv of Nx and on the hyperalgesia produced by 1mg/kg iv of Nx.
Results and discussion: The hyperalgesic effect of high doses of Nx was significantly reduced by 50% after the injection of the δ-antagonists. This suggests the involvement of δ-opioid receptors in a tonic inhibitory control exerted on nociceptive messages by endogenous opioid. The paradoxical effect of low doses was almost abolished by the κ–antagonist (85% decrease of the analgesic effect). This involvement of the κ–receptors supports as previous biochemical studies (2) the hypothesis of presynaptic κ–receptors which may modulate the release of endogenous opioid.
Conclusion: In this model of persistent pain, the bidirectionnal effect of Nx involves the δ-receptors for the hyperalgesia and the κ–receptors for the paradoxical analgesia.

A.115

EFFECT OF MORPHINE ON A NOCICEPTIVE FLEXION REFLEX IN PATIENTS WITH POSTOPERATIVE PAIN

Marcel Chauvin - Frédéric Guirimand, Pascal Gauneau, Claude Lebrault
Department of Anesthesiology, Hôpital Ambroise Paré,
92104 BOULOGNE Cedex, France

Background and goal of study: Intravenous (IV) morphine was shown to depress selectively the lower limb nociceptive flexion (RIII) reflex in volunteers (1) and in chronic paraplegic subjects (2), suggesting that IV morphine exerts a direct spinal inhibition of nociception. However, the time course of this spinal antinociceptive action was not evaluated in comparison with the duration of analgesia, and the extrapolation of these data to painful patients remains questionable . The present work was undertaken to assess the spinal effect of an IV dose of morphine in patients with postoperative pain.

Materials and methods: 20 adult ASA I or II patients, studied during the postoperative period were randomly assigned in a double blinded fashion either to group M (n = 10) which received IV morphine (0.16 mg/kg), or group P (n = 10) which received IV placebo (5 ml of isotonic saline solution) when they complained of severe pain. The intensity of postoperative pain was assessed on a visual analog scale (VAS). RIII reflex was studied according to a method previously described (1). The recruitment curves were recorded before, and at intervals after IV injection. A constant intensity of 1.2-1.3 times threshold (Tr) was applied between the recruitment periods. Data are reported as mean ± SD. Statistical analysis used paired or unpaired Student's t-test as required.

Results and discussion: Results are summarized in the table. Tr increased and the slope of the recruitment curve decreased in all group M patients. These changes were significant at 15 and 30 min. The decrease in RIII reflex under constant stimulus intensity appeared at 2 min and was significant during 30 min; the maximum decrease, seen at 5 ± 1 min, was of 86 ± 7%. By contrast, pain relief lasted 4 hours. Placebo study was stopped after 15 min because analgesics were required. This study demonstrates that in patients with postoperative pain, IV morphine produces a depression in RIII reflex at the dose of 0.16 mg/kg. These data support the hypothesis that, at this dose, IV morphine has a direct effect within the spinal cord. However, this spinal effect had a more limited duration than the pain relief, suggesting that the supraspinal action of IV morphine lasts longer than the inhibitory action at the spinal site.

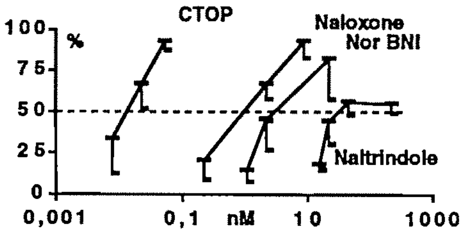
A.116

INVOLVEMENT OF μ, δ, and κ RECEPTORS IN THE INHIBITION BY INTRATHECAL MORPHINE OF A C-FIBRE EVOKED REFLEX IN THE RAT.

F. GUIRIMAND*, M. STRIMBU, J.C. WILLER**, D. LE BARS, INSERM, U-161, 75014 Paris, *Dép. Anesthésie; Hôp. A. Paré, 92100 Boulogne, ** lab. Neurophysiologie, Hôp. Pitié-Salpétrière, 75013 Paris.

By means of specific μ (CTOP), δ (naltrindole) and κ (nor-BNI) antagonists injected intrathecally, we studied the involvement of the opioid receptors in analgesia due to morphine at the spinal level. The nociceptive response was a C-fibre evoked reflex elicited by single-square electrical shocks (2 ms, 0.16 Hz) applied to the territory of the sural nerve of intact halothane anesthetized (0.9 %) rats. EMG-evoked responses, recorded by means of a pair of Pt-Ir electrodes inserted transcutaneously in the ipsilateral biceps femoris, were digitized, fullwaved rectified and C-fibre responses (at 3x threshold) were integrated in an adequate window (100 - 450 ms). Morphine was injected intrathecally in a dose (2.2 nM) that completely inhibited the reflex. Naloxone (0.22 - 8.8 nM) reversed the effect of morphine dose-dependently, with an ED_{50} = 1nM. The corresponding dose-response curve for naltrindole (15.4 - 220 nM) was shifted to the right (ED_{50} = 34.4 nM) with a maximal effect of 56 %. As expected, the dose-response curve corresponding to CTOP (0.0055 - 0.055 nM) was shifted to the left (ED_{50} = 0.01 nM). More surprinsingly, the specific κ antagonist nor-BNI (1.1 nm - 22 nM) also fullly reversed the effect of morphine dose-dependently (ED_{50} = 4.32 nM). The results confirm the importance of μ receptors in morphine-induced analgesia. The involvement of δ and κ receptors is possible, although an effect of nor-BNI on μ receptors cannot be excluded.

Our conclusion is that the C-fibre evoked reflex is a model with high applicability in evaluating the effect of putative analgesic drugs.



A.117

ISOPROTERENOL REVERSES THE MAC DECREASING EFFECT OF ESMOLOL IN RATS.

Azriel Perel, Alexander Shneider, Walter Kohn,
Department of Anesthesiology, Sheba Medical Center,
[Sackler School of Medicine, Tel Aviv University],
Tel Hashomer 52621, Israel.

Background and goal of study: Beta adrenergic blocking agents are known to have a depressive effect on the central nervous system. Although propranolol has not been found to reduce MAC of halothane in dogs (1), we have recently found that esmolol, a new short acting beta blocker, reduced MAC of halothane in rats (2). In addition, Kochs et al have shown that esmolol attenuates the EEG response to sensory stimulation in dogs, and that this effect was reversed by epinephrine (3). We have thus examined whether the MAC reducing efffect of esmolol is dose-dependent and whether it can be reversed by isoproterenol (ISOP).

Materials and methods: Thirty five 280-350g Sprague-Dawly male rats were included in the study and divided into 4 groups: 1. A control group (n = 10). 2. A group that received a continuous drip of 250 mcg/kg/min of esmolol (E250) (n = 8). 3. A group receiving 500 mcg/kg/min of esmolol (E500) (n = 8). 4. A group that received in addition to E500, a continuous infusion of ISOP in a dose that normalized heart rate to its pre-esmolol values. The MAC of halothane was determined by the tail clamp method in each group.

Results: Esmolol reduced the MAC of halothane in a dose dependent fashion (fig), the MAC decreasing from 0.97% during baseline (BL), to 0.84 and 0.74 during the administration of E250 and E500 respectively. The addition of ISOP (2.9±0.4 mcg/kg/min) to E500, brought MAC back to control values. The systolic blood pressure (at 0.9% halothane) was reduced from 152±16 to 122±10 and 109±10 mm Hg during E250 and E500 respectively, and returned to normal levels with isoproterenol. The changes in HR are shown in the figure. There was no change in the arterial blood gases at any point in the study.

Discussion and conclusions: The most probable explanation for the MAC reducing effect of esmolol is a decrease in the catecholamines content in the brain. Other studies which abolished central noradrenaline secretion have also produced about 35% decrease in the MAC of halothane (4). Isoproterenol is known to increase central catecholamines content and, most probably, counteracts the MAC decreasing effect of esmolol by this mechanism. The decrease of anesthetic requirements by a short acting beta blocker offers exciting possibilities in the administration of adequate nesthesia without using excessive amounts of conventional anesthetic agents.

EFFECT OF ESMOLOL VERSUS LIDOCAINE ON INTRACRANIAL PRESSURE AND HAEMODYNAMIC RESPONSES TO LARYNGOSCOPY AND INTUBATION

Toufik SAMAHA, Patrick RAVUSSIN*, Chantal CLACQUIN, Claude ECOFFEY

Anaes Dpt, Hôpital de Bicêtre, Université Paris - Sud, 94275 - Le Kremlin Bicêtre, FRANCE, and
* Anaes Dpt, CHUV, CH - 1011 Lausanne, SWITZERLAND

Background and goal of the study : The prevention and control of acute increases in intracranial pressure (ICP) and mean arterial pressure (MAP) in response to nociceptive stimuli are among the main aims of neuroanaesthesia. Lidocaine (1) and more recently esmolol (2) have been advocated to be given prophylactically 90 to 180 sec before application of a noxious stimulus like intubation. The present study was undertaken to compare both agents in neuroanaesthesia during the induction phase with special attention focused on MAP and ICP variations during intubation.

Material and methods : 22 patients for elective cerebral tumor resection were included in this randomized, double-blinded study, after IRB approval and informed consent. Exclusion criteria were ICP > 25 mmHg, CV disease and obesity (> 25 % IBW). The patients were assigned to 2 groups: Group I n = 11 esmolol (E) 1.5 mg/kg, Group II n = 11 lidocaine (L) 1,5 mg/kg. Monitoring included MAP, ICP via a lumbar spinal catheter, CPP (= MAP - ICP), PetCO$_2$ (to 33-35 mmHg). Since no patient had an intracerebral lesion which might have been an obstacle to CSF flow, CSFP changes were taken to indicate ICP changes. General anaesthesia was induced in both groups over a period of 5.5 min: thiopentone 5 mg/kg followed by isoflurane 0.5 %, fentanyl 1 µg/kg and vecuronium 0.1 mg/kg. At T1 Group I received E and Group II received L both over 20 sec. In both groups, 130 sec after the end of E or L administration laryngoscopy was started by the same intubator. Isoflurane was titrated to maintain CPP above 60 mmHg. Ephedrine 5 mg was used each time CPP dropped below 60 mmHg. ICP, MAP,HR and CPP were recorded at baseline (T0), after thiopentone (T1), after E or L administration (T2), during intubation (maximal values) (T3) and 5 min after intubation (T4). Analysis of variance with Sheffe F-test and student's t-test were performed for statistical analysis.

Results and discussion : The demographic data and baseline ICP, MAP, HR and CPP were similar in E and L. The evolution of HR was similar in both groups. Four patients were given ephedrine in each group. All the results (mean ±SD, mmHg) are summarized in the table (* $p < 0.05$ vs T0).

		T0	T1	T2	T3	T4
MAP	E	103±14	84±10	75±11*	116±22	83±13
	L	106±16	87±11	80±11*	115±16	90±18
ICP	E	11±6	12±7	13±8	17±10*	9±3
	L	10±6	10±4	11±5	16±8	11±6
CPP	E	92±11	71±9	61±8*	99±23	71±10
	L	96±11	76±14	68±14*	98±17	81±18

In normotensive neurosurgical patients both L and E when added to a classical anaesthetic sequence decreased CPP to values close to 70 mmHg for L and 60 mmHg for E. Both agents during laryngoscopy and intubation protected the patients from increases in MAP and CPP as compared to baseline whereas only L (and not E) protected ICP to such increases.

Conclusion : Lidocaine seems to offer more stable MAP and CPP values during induction and a better protection for ICP increases during laryngoscopy and intubation than esmolol.

A.119

EFFECTS OF INTRATHECAL MEPERIDINE (MP) FENTANYL (FN) AND LIDOCAINE (LD) ON SOMATOSENSORY (SSEP) AND CORTICAL MOTOR (CMEP) EVOKED POTENTIALS IN HUMANS.

S Fernandez, J Monells*, JM Espadaler*, MM Puig

Departments of Anaesthesiology and Neurophysiology*,
Hospital del Mar, Autonomous University
of Barcelona, Spain.

The aim of the present study was to establish the effects of clinically relevant doses of LD, MP and FN on somaesthetic and motor pathways, when administered in the lumbar subarachnoid (SA) space.

Methods: Thirty ASA I-II patients (45-65 y.o.) scheduled for infraumbilical surgery entered the study. Institutional and individual consents were obtained. Drugs were administered SA (2 ml, in D7.5W) at L3-4 with a 25G needle. Patients were randomly distributed into three groups which received: LD (1 mg/kg), MP (1 mg/kg) or FN (25 ug). SSEP were obtained by stimulating the posterior tibial nerve and registered at Fz-Cz. CMEP's were elicited by magnetic stimulation at the vertex and muscle responses, at rest and facilitated, recorded from the gastrocnemius. The conduction of the motor radicular segment was assessed by the F waves. All four evoked responses (ER) were elicited from each patient in baseline conditions and 30 min after treatment; we evaluated the number and characteristics (amplitude, latency) of the ER.

Results: In baseline conditions, forty ER could be elicited from each group (n=10). After treatment, ER's were either blocked (type A), altered (type B, decreased amplitude and/or increased latency) or unchanged (C). The Table shows frequency distribution and type of response in each group.

	A	B	C
LD	40	0	0
MP	19	19	2
FE	0	27	13

By chi-square, each group was different from the others ($p<0.01$).

Our results also show that MP predominantly blocked motor responses at rest (CMEP-R) while FE altered both sensory and motor ER. The study demonstrates that clinically relevant doses of SA opiates alter motor and sensory transmission in the spinal cord.

SSEP were obtained by stimulating the posterior tibial nerve and registered at Fz-Cz. CMEP's were elicited by magnetic stimulation at the vertex and muscle responses, at rest and facilitated, recorded from the gastroecnemius. The conduction of the motor radicular segment was assessed by the F waves.

A.120

SLOW-RELEASE EFFECT OF pH-ADJUSTED BUPIVACAINE: PHARMACOKINETIC DEMONSTRATION

Dan Benhamou, Jean-Marc Malinowsky,
Valérie Quinquis, Philippe Bourget, Guy Couarraze

Département d'Anesthésie-Réanimation Chirurgicale,
Hôpital Antoine Béclère, Université Paris-Sud,
92141 Clamart, France

Background and goal of study: It has been recently demonstrated *in vitro* that pH-adjustment of local anaesthetics used during regional anesthesia is associated with a slow-release effect (1). Intramuscular injection (which usually provides pharmacokinetic data close to those obtained after epidural injection) of pH-adjusted bupivacaine (BUP) was used to determine *in vivo* the extent of changes in pharmacokinetic parameters indicative of a slow-release effect.

Materials and methods: 21 New-Zealand white non fasting rabbits (weight: 2.5-3.2 kg) were premedicated with 2-4 mg of midazolam and then immobilized. Cannulation of an ear vein (22g catheter) and of a femoral artery (20g catheter) were performed under local anesthesia with lidocaine. A radiant heat lamp was used to maintain normothermia. An intramuscular injection of 3 ml/kg of 0.5 % BUP was injected according to the randomization order : **group 1** : plain bupivacaine (pH = 5.80 ± 0.02), **group 2** : BUP alkalinized with 0.1 mEq bicarbonate/20 ml BUP (pH = 6.8 ± 0.01), **group 3** : BUP alkalinized with 0.2 mEq bicarbonate/20 ml BUP (pH = 7.2 ± 0.02). Arterial blood samples (1-1.5 ml) were withdrawn at 2, 5, 10, 15, 30, 60, 90, 120, 240 and 480 min after im injection. Plasma BUP concentrations were measured using HPLC and pharmacokinetic data were calculated using a computer-assisted program. Statistical analysis was performed using ANOVA for repeated measures.

Results and discussion: Peak plasma concentration (Cmax) was significantly decreased in group 3 (pH = 7.02) suggesting slow release and absorption from the im site of injection (table). The area under the curve (AUCo-∞) was significantly lower in both groups with pH-adjusted BUP suggesting important tissue storage (table).

Conclusion: This pharmacokinetic study confirms that pH-adjustment of bupivacaine is associated with a slow-release effect which might explain the prolonged duration of sensory block after regional anesthesia.

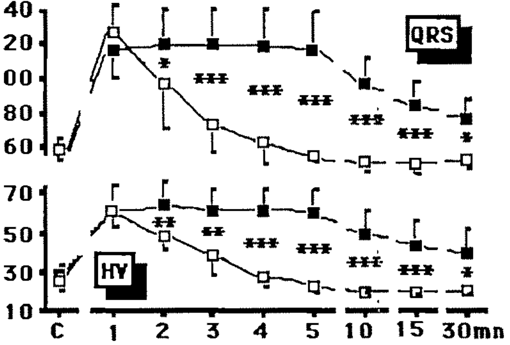
LEMAKALIM REVERSES VENTRICULAR CONDUCTION IMPAIRMENT INDUCED BY A LARGE DOSE OF BUPIVACAINE IN ANESTHETIZED DOGS

JE. de La Coussaye, JJ. Eledjam, P. Bruelle, P. Peray,
A. Sassine.
Departments of Anesthesiology, and of Biostatistics,
University Hospital of Nîmes Laboratory of
Cardiovascular Physiology, Medical School of
Montpellier, France.

Background and goal of study: Large doses of bupivacaine (B) induce dramatic slowing of ventricular conduction which facilitates the occurrence of conduction block and reentrant arrhythmias (1). It is established in anesthetized dogs that a large dose of B induces marked His-Ventricular interval (HV) lengthening, QRS widening and decrease in $LVdP/dt_{max}$ (2). As we previously observed in dogs that lemakalim (L), a potassium channel opener, shortened HV and QRS, the aim of the study was to analyse the effects of L in dogs given a large dose of B.

Materials and methods: Twelve anesthetized and mechanically ventilated mongrel dogs were allocated in 2 groups (n=6). In addition to ECG lead 2, His bundle electrogram via a bipolar electrode and left ventricular and aortic pressures via a double high fidelity micromanometer were recorded. All dogs were given 0.2 mg/kg iv atropine and then 4 mg/kg iv B over 10 s. Group 1 was the control group. In addition, group 2 was given 0.03 mg/kg iv L from 1 mn to 2 mn after B injection. The monitored parameters were: Sinus cycle length (RR, msec), QRS duration (msec), atria-his (AH) and HV intervals (msec), QTc interval, mean aortic pressure (MAoP, mmHg) and the first derivative of systolic left ventricular pressure ($LVdP/dt_{max}$, mmHg/s). There were recorded before B injection (C) and then 1, 2, 3, 4, 5, 10, 15 and 30 min after B injection. Data were expressed as mean ± SD and 2-w.ANOVA (repeated measures) + contrast were used.

Results and discussion: B induced significant RR, AH, HV and QTc lengthening, QRS widening, and decrease in MAoP and in $LVdP/dt_{max}$. Fig shows that L significantly improved B-induced QRS and HV changes. L also significantly shortened QTc. RR, AH, MAoP and $LVdP/dt_{max}$ were not significantly modified by L.



■= Bupivacaine; □= Bupivacaine + Lemakalim;
* p<.05, ** p<.01, *** p<.001

Conclusion: L reversed B-induced ventricular conduction and repolarization impairments in anesthetized dogs and could protect against reentrant arrhythmias.

A.122

MOTOR BLOCKADE AND ABSENCE OF LOCAL NERVE TOXICITY INDUCED BY LIPOSOMAL BUPIVACAINE INJECTED INTO THE AXILLARY BRACHIAL PLEXUS OF RABBITS.

Franz J. Legros, Noelle Lafont, Michel Donnay, and Jean Boogaerts.
Laboratory of Physiopathology, Free University of Brussels, Brussels, Belgium.

Background and goal of study: Bupivacaine has been encapsulated into multilamellar liposomes in order to reduce its systemic toxicity (1) and to lengthen its action. Low, constant and sustained plasma levels have been observed after epidural and axillary brachial plexus injection. The motor block effect and the possible neurotoxicity of liposomal bupivacaine applied *in vivo* to intact peripheral nerve bundles were studied in rabbits.

Materials and Methods: Five milliliters of sterile solutions containing 0.75% bupivacaine encapsulated in 42.5 and 85 mg of multilamellar liposomes made of phosphatidylcholine and cholesterol in a molar ratio 4:3 were administered to rabbits at the level of the brachial plexus located using a seeking electrode to elicit motor movement of the paw. Same doses of empty vesicles were given to control animals. The rabbits were put on the floor at 20-min intervals after injection, and an attempt was made to walk them.

Results and discussion: An immediate motor blockade of the fore limb lasting for 10 hours was measured after injection of the liposomal drug. Empty liposomes did not induce motor block. No animal developed permanent hind limb paralysis. Electron microscopy analysis of the nerves after 2 and 7 days showed no changes of the myelin sheaths and no alteration of unmyelinated fibers after injection of liposomal bupivacaine or empty liposomes

Conclusion: The pharmacologically active liposomal formulation of bupivacaine did not induce any neurological deficit nor alterations of the local nerve tissues.

A.123

THE EFFECTS OF BUPIVACAINE, MEPIVACAINE AND PRILOCAINE ON PLATELET AGGREGATION

Nurettin Bayhan, M Erdal Güzeldemir, Hülya Türkan

Department of Anaesthesia and Intensive Care,
Gülhane Military Medical Academy and Faculty,
Ankara, Turkey.

Background and goal of study: Venous thromboembolism is a common postoperative complication (1). The factors involved are complex and their mechanisms have not been exactly elucidated. It was found that blood loss in patients receiving extradural analgesia was decreased significantly. The inhibitory effects of different kinds of local anaesthetics have been reported (2). In this study, the effects of bupivacaine, mepivacaine and prilocaine on platelet aggregation were studied.

Materials and methods: The study included 33 patients, 11 for each agent, in whom elective surgery was performed under extradural anaesthesia. None had any haematological disease. For two weeks before study, the patients had received no medication and no premedication was given. After inserting an extradural catheter, 100 mg bupivacaine, 400 mg mepivacaine or 400 mg prilocaine were administered to achieve extradural anaesthesia. Blood samples were obtained before inserting the extradural catheter and one hour after the anaesthetic agent had been given. Surgery was delayed until after the one hour sample was taken, and no drugs or fluids were given during that hour. For measurement of platelet aggregation, the Sigma protocol was used.

Results and discussion: ADP, collagen, epinephrine and PAF (platelet activating factor)-induced platelet aggregation were not decreased by local anaesthetic agents.

Conclusions: In contrast to previous reports on this subject, bupivacaine, mepivacaine and prilocaine have no effect on platelet aggregation when used for extradural anaesthesia in conventional doses.

A.124

THE EFFECTS OF EPIDURAL AND SPINAL ANESTHESIA ON THE CHANGES IN THE PLETHYSMOGRAPHIC SIGNAL IN THE LOWER AND UPPER LIMBS

Sergei Preisman, Ilan Eldar, Azriel Perel

Department of Anesthesiology, Sheba Medical Center, Tel Hashomer, Israel [Sackler School of Medicine, Tel Aviv University.]

The onset of sympathetic block after regional anesthesia is characterized by vasodilation. The resulting increase in peripheral blood flow can be detected by the change in the plethysmographic signal (PLETH) of the anesthetized limb (1). We therefore attempted to examine the following questions: a) Will 1 ml of .5% spinal marcaine (marc) produce a significant change in the PLETH? b) Can the response of the PLETH differentiate between epidural and spinal anesthesia? c) Can the ratio of the PLETH of the upper to lower limb be of help in determining the onset of the sympathetic block?

Twenty five ASA 1-2 patients (mean age 67, range 19-91 years) scheduled to undergo urological (23), orthopedic (1) and general (1) procedures were monitored by two sensors of pulse oximeters (Datex Helsinky, Finland) that were placed on the thumb and second toe. The PLETH display of these monitors allows the measurement of the true PLETH amplitude. After two minutes of baseline monitoring in the sitting position, an epidural (18.7 ± 1.4ml of 0.5% marc) (n = 11) or spinal (2.4 ± 0.2 ml of 0.5% marc) (n = 14) blocks were performed. Four of the patients in the spinal group received one ml of 0.5% marc, followed by the rest of the dose after 3 minutes. After the termination of injection all patients were brought to the supine or lithotomy position. Sedation included 1-2 mg of IV midazolam (M) on demand during the procedure. At the termination of surgery the trended PLETH were recorded by a video printer and analyzed.

One ml of 0.5% marc did not change in the lower limb (LL) PLETH. There was no difference in the latency (time from injection to beginning of change of PLETH) between spinal (5.1 ± 4.2 min) and epidural (4.5 ± 2.3 min), and in the time to peak response (spinal 21.9 ± 16.3 vs epidural 31.5 ± 18.9 min, P < .1). The LL PLETH increased by 790 ± 1522% after spinal, and by 787 ± 415% after epidural, relative to baseline PLETH amplitude. In 8\14 patients in the epidural and 5\11 in the spinal group upper limb PLETH did not change or decreased. In the other patients it increased significantly especially after IV midazolam (M) (see Fig).

The intrathecal administration of 1ml of marc did not produce any changes in the LL PLETH. Thus monitoring LL PLETH cannot allow the reduction of the dose of marc currently used as a "test dose" during epidural block. The LL PLETH could not distinguish between spinal and epidural blocks, mainly due to the variable status of the peripheral circulation in our elderly patient. Although the response of upper limb PLETH was extremely variable, it proved useful as an indirect measure of sedation.

A.125

THE EFFECT OF PARENTERAL DICLOFENAC AND MORPHINE ON EFFICACY DURATION AND HEIGHT OF BLOCKADE DURING CONTINUOUS EPIDURAL BUPIVACAINE 0.5%.

D Forbes, A Binning, NB Scott

Division of Anaesthesia, Glasgow Royal Infirmary, Scotland

Background and goal of study: Postoperative pain involves an increase in afferent input from the wound to the spinal cord with time, which may be reduced by intramuscular diclofenac given preoperatively and continued postoperatively. This may prolong the duration of epidural blockade, in addition to improving pain relief. Systemic morphine has been shown to enhance quality and duration of epidural bupivacaine. The purpose of this double-blind randomised trial was to determine (a) whether intramuscular diclofenac could influence the duration of continuous epidural bupivacaine 0.5% and (b) whether intravenous morphine altered the height of epidural blockade during a continuous infusion.

Patients and methods: In 26 hysterectomy patients (ASA 1-3) a block to T4 was established preoperatively and a continuous infusion of 0.5% bupivacaine 8 ml/h ran for 14 h. 13 patients received diclofenac im and 13 im saline. Height of blockade and pain scores on a 5-point scale were measured hourly. If the block regressed to T10 and/or the pain score was 2 or more, 10 mg of morphine was given intravenously and the height of the block reassessed. 16 patients received morphine in this manner.

Results: Age, weight and loading dose of bupivacaine 0.5% were similar in the two groups. Although duration of blockade was not significiantly prolonged (p=0.087), pain scores were significantly reduced by the use of im diclofenac (p=0.0087). Intravenous morphine (10 mg) did not alter the height of epidural blockade.

Conclusion: Epidural bupivacaine and im diclofenac appeared to act additively on postoperative pain.

NINE YEARS OF CLINICAL EXPERIENCE WITH 29 GAUGE SPINAL NEEDLES

Martin Dittmann, Hans-Gerhard Schäfer,
Felix Renkl, Imrich Greve

Department of Anaesthesia and Intensive Care,
Kreiskrankenhaus, D-7880 Bad Säckingen,
Germany

Background and goal of study: 29 - gauge Quincke needles reduce the incidence of postspinal headache, but are said to be difficult to use, especially for trainees. The introduction of these needles into routine practice has allowed an assessment of their performance in a large series of patients.
Material and methods: 2293 patients receiving spinal aneasthesia were prospectively and blinded studied in a period between 1983 until 1992. All patients were followed up 3 - 5 days after surgery by an anaesthesiologist not involved in giving the spinal anaesthetic. The difficulties encountered by trainees were assessed.
Results and discussion: The overall incidence of postspinal headache was 1,2 % . The highest rate was found in the age group 30 - 39, when it was 2,5 % . No great technical difficulties were encountered and trainees became adept in its use within 6 - 8 weeks .
Conclusion: 29 - gauge spinal needles are suitable for routine use and are associated with a low incidence of postspinal headache.

A.127

INCIDENCE OF POST DURAL PUNCTURE HEADACHE IN YOUNG ADULTS BY THE USE OF THE SPRÔTTE NEEDLE: 300 PATIENTS.

C. Descraques,G. Mion, Y. Auroy,B. Lenoir,B. Pats,B. Rouvier,J.P Chabanne

Department of Anaesthesiology, BEGIN Military Hospital Saint-Mandé, France.

Introduction: The configuration of the needle tip is an another approach to reduce the incidence of post dural puncture headache (PDPH) [1]. The Sprötte needle has been use for 4 years in our department and its use is associated with a low incidence of PDPH. The purpose of this study is to verify prospectively the low incidence of PDPH in young patients by the use of this needle.

Materials and methods: After obtaining informed consent and approval from the hospital Ethics committee, we evaluated 300 patients (264 males and 36 females) undergoing spinal anaesthesia for 262 orthopaedic operations and 38 visceral operations. The mean age was 29 ± 9 years (aged 18-50 years), the height was 175 ± 7 cm and the weight was 73 ± 11 kg. The needle was inserted by a physician 111 times and an anesthest nurse 189 times. The introducer needle was inserted in sitting position (268 times) or in lateral position (32 times). The diameter of the needle was 24G (284 times) or 22G (16 times). The local anesthesic was hyperbaric bupivacaïne 280 times(14,5 mg ± 2 mg) or hyperbaric xylocaïne 20 times (85,3 mg ± 2,9 mg). The patients were hydrated with 602 ml ± 253 ml lactated Ringer' s solution and no abundant hydration was prescribed postoperatively. The patients were questioned every day by an anaesthetist for headaches until the exit from hospital. A headache was considered to be a PDPH if it was postural in character.

Results: The puncture has been single (249 times),double (34 times) or multiple (17 times) with a mean of 1,27 ± 0,69. The incidence of failed anaesthesia has been 4,7 % (all received general anaesthesia). The patients started to get up the 1,0 ± 0,3 day and were questioned during 3,8 ± 1,7 days. Among the 23 headaches we observed, 8 were due to PDPH. They were moderate and responded to bed rest and analgesics. The average duration was 2 days but one headache occurred within 20 days and lasted 1 month[2].

Conclusion: The spinal anaesthesia is easy to perform in 93,7 % of cases with the Sprötte needle which is characterised by a blunt ogival tip and a lateral orifice [3]. This needle is associated with a low incidence of PDPH (2,7%) in young adults and allows a wider use of spinal anaesthesia on this population.

A.128

POSTDURAL PUNCTURE HEADACHES ARE NOT RELATED TO THE DURATION OF SPINAL CATHETER PLACEMENT

N. Liu*, A. Montefiore**, N. Kermarec*, L. Beydon*, F. Bonnet*,
*Anesth. Dept., Henri Mondor Hospital, 94010 Créteil,
**Tenon Hospital, Paris-France

Introduction : Continuous spinal anesthesia (CSA) is commonly performed with large sized needles. The resulting dural hole may be responsible for postdural puncture headache(PDPH). Recently Denny et al.[1] have suggested that spinal catheter placement prevented PDPH due to a local oedema which searled the hole after catheter removal. The current study was conducted to assess the incidence of PDPH after CSA and the preventing role of keeping the catheter in place.

Material and Methods : 87 patients scheduled for lower limb orthopaedic surgery were included in this prospective study after informed consent and approval from our ethical committee. CSA was performed with a 18G Tuohy needle allowing the insertion of a 20G spinal catheter. Incremental doses of isobaric 0.5% bupivacaine were injected. At the end of the surgical procedure, patients were allocated randomly into 2 groups. In group 1 the catheter was removed immediately. In group 2 the catheter was removed 12 to 24 hours later. Postoperatively, patients were asked for headache twice a day during the first 3 postoperative days and on the 8th day. Statistiscal analysis used the Student's t-test, the Chi-square test, and the Dunnet and Gent Chi-square test when appropriate; $p<0,05$ was considered significant.

Results : The 2 groups were comparable for demographics (mean ages: 68.5±13.9 and 71.2±9.6 years respectively in groups 1 and 2), total amount of fluids infusion, and postoperative analgesic requirements. Duration of catheter placement was 4.0±1.8 hour and 22.7±4.0 hour in groups 1 and 2 ($p<0,01$). Typical PDPH occured in 8 patients (9.2%), 5 in group 1 and 3 in group 2 (NS). One patient (group 2) required a blood patch, the other patients were treated with analgesics and bed rest. The two therapeutic alternatives were equivalent for prevention of headache ($p<0,05$).

Discussion : Compared to previous data[1] this prospective study documents a higher incidence of PDPH after CSA. Although this study does not completely exclude any effect of the catheter it seems to be of no clinical significance. The hypothesis of an oedema induced by the catheter placement and occluding the dural hole is not supported by these results.

A.129

EPIDURAL BLOOD PATCH FOR TREATMENT OF POSTDURAL PUNCTURE HEADACHE

Per H. Rosenberg, Tomi Taivainen, Mikko Pitkänen, Marjatta Tuominen

Department of Anaesthesia, Surgical Hospital, University Central Hospital, Helsinki, Finland

Background and goal of study: Epidural blood patch (EBP) has gained wide acceptance as a treatment of choice for postdural puncture headache (PDPH). However, the optimal volume of blood for a patch has remained controversial. There are only a few studies concerning the long-term-effects of EBP [1-2]. Our goal was to evaluate the efficacy of different volumes of EBP for treatment of PDPH.

Materials and methods: 81 consecutive patients with PDPH were studied prospectively in two parts. In Study part I 10 ml of blood was injected for EBP in 28 patients. In Study part II the patients received randomly either an amount of 10 ml (27 patients), or 10-14 ml (26 patients) according to the height of the patient. EBP was considered initially successful if PDPH disappeared completely during the 2-h recovery room follow-up. To evaluate the long-term success a questionnaire was mailed to all patients 4 weeks after EBP. The statistical analyses consisted of Student t-test and chi-square test.

Results and discussion: The EBP performed 3.7±2.9 (mean±sd) days following the dural puncture, was initially successful in 88-96% of the patients in different study groups. In the questionnaire, however, only 50-68% of the patients reported that PDPH had disappeared immediately without recurrence. In 16-36% of the patients the PDPH returned at lesser intensity and in 14-17% PDPH was reported to have continued, disappearing gradually. However, 87% of patients were satisfied with the EBP treatment. There were no statistically significant differences between the groups. The results indicate that a larger height-adjusted volume of blood for EBP in adults does not produce a better effect on PDPH compared to a standard 10 ml volume.

Conclusion: Our results indicate that a larger volume of blood than 10 ml for EBP has no therapeutic benefit in the treatment of PDPH. Therefore, we recommend the volume of 10 ml of blood for routine EBP therapy.

SEQUENTIAL SPINAL PERIDURAL ANAESTHESIA FOR GYNAECOLOGICAL SURGERY UNDER LAPAROSCOPY

Stéphane Joos, Richard Quintilla, Roland Servais

Clinique Champeau, Beziers, France

INTRODUCTION : loco-regional anaesthesia technics for laparoscopy are generally considered as unsatisfactory. Shoulder pain and respiratory problems are the main disadvantages. The recent clinical availability of 29 G needles for the combined spinal-peridural technic permits a new approach of the anaesthetic management for laparoscopic procedures in young healthy people.

METHOD : after written informed consent 50 females between 25 and 40 years, scheduled for gynaecological surgery under laparoscopy benefited from a combined spinal-epidural technic. After puncture between L2-L3 and detection of the peridural space,spinal anaesthesia was realised with a 29 G needle introduced through the peridural needle in the subarachnoid spaces. A mixture of 50 mg xylocaine 5 % 1cc, bupivacaine 0,25 % plain 10 mg 4cc and sufentanil 7,5 mcg was administered intraspinally. All patients were awake (n:14) or under extremely light sedation (n:36) and breathing oxygen by mask. The following variables. were recorded : 1° - Evaluation of clinical efficacy of the anaesthesia. 2° - the haemodynamic and respiratory repercussions during the procedure by measuring : pulse - BP - oxygen saturation and blood gasses. 3° -post operative complications.

RESULTS : the results were excellent in 94 % of all cases and directly related to the level of anaesthesia (T2-T3). The haemodynamic changes after preventive administration of 1.000 ml of Ringer Lactate and 30 mg ephedrine were unsignificant. No clinical respiratory depression was noted. Oxygen saturation remained higher than 94 %. There was no significant change in Pa02. Even after more than 45 min C02 insufflation pH and PC02 mean modifications did not exceed respectively 1% and 14% of the preinsufflation values.

DISCUSSION : the good results are probably due to the excellent quality of the abdominal relaxation obtained by the spinal anaesthesia combined with the elective action of sufentanil on visceral pain. The insuflation rate however must be slow and the intra-abdominal insuflation pressure kept below 12 mmHG.

CONCLUSION : provided the patient is well informed, sequential spinal peridural anaesthesia is suitable for gynaecological surgery under laparoscopy and offers all the advantages of the loco regional anaesthesia technics.

A.131

SUBARACHNOID ANAESTHESIA (SAA) AND POST-OPERATIVE ANALGESIA WITH BUPIVACAINE (BV) PLUS FENTANYL (FN) IN GERIATRIC PATIENTS

D Fernandez, C Castells, M Rue, M Bernaus, MM Puig*

Depts of Anaesthesiology, Hospital de Sabadell
and *Hospital del Mar, Autonomous University
of Barcelona, Spain

The aim of the present study was to establish the characteristics of the association of BV with FN when used during SAA in geriatric patients.

Methods: Forty ASA II-III patients (71-86 y.o.) scheduled for total knee (TKR) or hip (THR) replacement under SAA entered the study. They were randomly distributed in two groups which received in a double blind manner, hyperbaric BV (12.5 mg) with (group II) or without FN (25 ug, group I) in a final volume of 3 ml. Institutional and individual consents were obtained. All patients were evaluated prior to surgery for: associated pathology and medication, chronic pain (VAS, Lattimen) and mental status (Eysenck, Hamilton, MMSE). SAA was given at L3-4 with a 22G needle; motor\sensory block, and side effects (respiratory depression, pruritus, nausea and vomiting and hypotension) were recorded intra-op. In recovery room, acute pain (VAS; facial expression test, FET) and MMSE were evaluated at the time of analgesic request (AR).

Results: There were no significant differences between groups regarding: demographic distribution, pre-op and post-op physical and mental evaluation, characteristics of SAA, duration of surgery and time of AR request. Global incidence of side effects was not statistically different among groups; however, the % of patients with pruritus (0 Vs 21.1%) was significantly higher in group II (p<0.05).

When intensity of pain (VAS, FET) was compared according to type of surgery, patients who received FN (group II) had significantly less pain at the time of AR. The results are shown in the Table

	VAS	FET	N
THR (I)	58.5+9.3	6.1+0.4	11
THR (II)	32.1+8.1*	5.2+0.6	12
TKR (I)	79.8+8.6	7.1+0.2	9
TKR (II)	37.5+12.9**	4.5+0.5**	8

*p<0.05 and **p<0.01 when compared to the same type of surgery in group I (N=number of patients)

Conclusions: Our results indicate that in geriatric patients, the association of BV and FN during SAA:

a) Improves post-operative analgesia

b) Does not alter the duration of motor/sensory block induced by BV

c) Increases intra-op pruritus

d) Does not alter the mental status of the geriatric patients.

A.132

FENTANYL OR BUPRENORPHINE SIDE EFFECTS IN SPINAL ANAESTHESIA

Roberta Foppoli, Paolo Lunghi, Zeffiro Bonara, Carla Mora, Raffaele Stacca .

**Department of Anaesthesia and Intensive Care
Carpi Italy**

Background and goal of study: The aim of this study was to compare the complication rate between two groups of elderly patients undergoing orthpaedic surgery using subarachnoid anaesthesia with hyperbaric bupivacaine and fentanyl or bupivacaine and buprenorphine.

Materials and methods: The study was conducted on 70 patients , 49 females and 21 males (ASA II - IV), with a mean age of 83.5 ± 5 years. Patients were randomised into two groups: the first (group B) received hyperbaric bupivacaine 1% 15 mcg/ kg and buprenorphine 2 mcg/kg, the second (group A) hyperbaric bupivacaine 1% at the same dosage as group B and fentanyl 1 mcg/kg. Spinal anaesthesia was performed at the L 3/4 level using a 25G Whitacre needle.

Results: Within the first hour, hypotension was observed in 11.4 % (4 patients) in group A , and in 46% (16 patients) in group B. Nausea and vomiting was not observed in group A, while one patient suffered from these problems in group B. Pruritis (of the trunk) was observed in three patients in group A and none in group B.

Conclusions: Buprenorphine/bupivacaine was associated with a higher incidence of hypotension than fentanyl/bupivacaine but caused less pruritis.

A.133

COMPARISON BETWEEN DOUBLE-BURST STIMULATION AND 50, 100 HZ TETANIC FADE DURING SPONTANEOUS RECOVERY OF VECURONIUM INDUCED NEUROMUSCULAR BLOCKADE

Michel J. Baurain, Boris S. Dernovoi, Alain A. d'Hollander, Denis M. Schmartz.

Anesthesiology Department, Hopital Erasme, Free University of Brussels, 1070 Brussels, Belgium.

Introduction: During recovery, tactile evaluation of the response to Double Burst Stimulation (DBS$_{3,3}$)[1] is superior to tactile evaluation of the response to train-of-four (TOF) stimulation[2]. The clinical perception of a sustained response to DBS stimulation does not always ensure adequate neuromuscular recovery as defined by a sustained response to 50 Hz tetani[3]. The purpose of this study is to compare DBS$_{3,3}$ to TOF, 50 and 100 Hz tetanic fade during spontaneous recovery of vecuronium induced neuromuscular blockade.

Methods and materials: Fourteen ASA I-II adult anesthetized (thiopental, fentanyl, N_2O) patients (with informed consent and approval by the Research Committee, Brussels Free University, Brussels, Belgium), undergoing elective surgery, were monitored (isometric adductor pollicis mechanical activity). Neuromuscular block was produced by vecuronium 100 µg/kg and additional doses of 20 µg/kg. At the end of surgery, the following variables were observed: twitch height was measured every 10 s and TOF (2Hz), every 3 min until TOF spontaneously regained 70%. 20 s later, a DBS was assessed ,followed by tetanic fade (50 and 100 Hz, 5 s duration, 1 min apart, sequentially assessed in a random fashion). Statistical analysis of the data was performed with the Wilcoxon Matched-pairs Signed-ranks Test, according to SPSS package programs. The comparisons were considered significant at 0.05 level.

Results: All results are summarized in table 1. When TOF ratio spontaneously regained 71±1%, DBS value (86%) is significantly lower than 50 Hz tetanic fade (92%), but higher than TOF ratio (71%) and 100 Hz tetanic fade (48%).

Conclusion: During spontaneous recovery of vecuronium induced paralysis in young anesthetized patients, DBS is more sensitive than 50 Hz tetanic fade but less sensitive than 100 Hz tetanic fade and TOF ratio to detect slight residual neuromuscular blockade, evidenced with instrumental recordings in place of purely clinical assessment.

A.134

REVERSAL OF VECURONIUM INDUCED NEUROMUSCULAR BLOCKADE: NO EFFECTS OF ATROPINE ADMINISTRATION TIMING.

Michel J. Baurain, Boris S. Dernovoi, Alain A. d'Hollander, P.C. Bollen.
Anesthesiology Department, Hôpital Erasme, Free University of Brussels, B-1070 Brussels, Belgium.

Introduction: Atropine is commonly used to block undesirable muscarinic effects of the anticholinesterase agents. The results observed in man[1] and cats[2] seem indicate that atropine may interfere with the neuromuscular junction. This study investigates this role in human clinical anesthesia, when atropine is given either simultaneously or prior to neostigmine administration to reverse a vecuronium induced paralysis.

Methods and materials: Twenty-four ASA I-II adult anesthetized (thiopental, fentanyl, N_2O) patients, (with informed consent and approval by the Research Committee, Brussels Free University, Brussels, Belgium), undergoing elective surgery, were monitored (isometric adductor pollicis mechanical activity). Neuromuscular block was produced by vecuronium 100 µg/kg and additional doses of 20 µg/kg. For reversal of paralysis, the patients were randomly divided into two groups of 12 patients each and received 15 µg/kg atropine either when twitch tension spontaneously regained 10% of its control value in the first group (TH10) or 25% of its control value in the second group (TH25). All the patients received a fixed dose of 40 µg/kg neostigmine when twitch tension spontaneously regained 25% of its contiol value. After neostigmine administration, the following variables were observed during a 15 min period: twitch height was measured every 10 s and train-of-four (2Hz), every 3 min. Immediately thereafter, tetanic fades -50 and 100 Hz, 5 s duration, 1 min apart- were assessed sequentially in a random fashion. Statistical analysis of the data was performed with the one-way analysis of variance test, according to SPSS package programs. The comparisons were considered significant at 0.05 level.

Results: All results are summarized in table 1. There are no significant differences between the two groups, for all the observed tests.

Conclusion: In the present study, atropine administration prior to neostigmine does not improve the neostigmine recovery from a vecuronium-induced neuromuscular blockade. In these clinical conditions, atropine administration timing appears of limited importance to optimize the reversal of neuromuscular transmission impairment in young anesthetized patients.

A.135

CAN REPETITION OF HIGH FREQUENCIES STIMULI ALTER THE VALUE OF 50 AND 100 HZ TETANIC FADE DURING VECURONIUM INDUCED NEUROMUSCULAR BLOCKADE?

Michel J. Baurain, Boris S. Dernovoi, Alain A. d'Hollander, Denis M. Schmartz.

Anesthesiology Department, Hôpital Erasme, Free University of Brussels, B-1070 Brussels, Belgium.

Introduction: Tetanic stimulation may condition subsequent low frequencies stimuli responses for a period of 6-30 min. Repeated administration of tetanic stimuli may demonstrate a false recovery from muscle relaxants[1]. Train-of-four (TOF) ratio and double-burst stimulation (DBS) returned to baseline within 2 min after a 5-s, 50-100 Hz tetanic stimulus[2]. A period of 5 min between sequential 50 Hz tetanic stimuli would be sufficient to ensure accurate assessment of tetanic amplitude or fade[3]. This study investigates possible conditioning of tetanic stimuli upon high frequencies (50 and 100 Hz) stimuli responses for a 1 min interval, either during spontaneous recovery or after neostigmine administration.

Methods and materials: Twenty-one ASA I-II adult anesthetized (thiopental, fentanyl, N_2O) patients (with informed consent and approval by the Research Committee, Brussels Free University, ULB, Brussels, Belgium), undergoing elective surgery, were monitored (isometric adductor pollicis mechanical activity). Neuromuscular block was produced by vecuronium 100 μg/kg and additional doses of 20 μg/kg. Tetanic fade - 50 and 100 Hz, 5 s duration, 1 min apart- were assessed sequentially in a random fashion 2 times at 1 min interval: in the first group (n=11), when TOF ratio spontaneously regained 70%, in the second group (n=10), 15 min after 40 μg/kg neostigmine i.v.. Statistical analysis of the data was performed with the Wilcoxon Matched-pairs Signed-ranks Test, according to SPSS package programs. The comparisons were considered significant at 0.05 level.

Results: There are no significant differences between the values (table 1) of 50 and 100 Hz tetanic fade before and after conditioning, either during spontaneous recovery or after neostigmine administration.

Conclusion: In the present clinical conditions, neuromuscular assessment can be performed by the use of a 5-s, 50-100 Hz tetanic stimulus without distorting subsequent 5-s, 50-100 Hz stimuli responses, after a 1 min period in young anesthetized patients.

DOES NICARDIPINE POTENTIATE THE NEUROMUSCULAR BLOCK OF ATRACURIUM ?

JE Bazin, T Gillart, A. Comte, C. Dubray, P Schoeffler

Département d'Anesthésiologie - Hôpital Gabriel-Montpied - 63000 Clermont-Ferrand. France

Nicardipine (N) have been proposed for deliberate hypotension in orthopedic surgery. Howewer, it has been reported that, in vitro and in man, some calcium channel blockers may exacerbate the effect of muscle relaxants (1). The aim of this study was to compare the atracurium neuromuscular block during deliberate hypotension induced either by N or by sodium nitroprusside (SNP) which does not interact with relaxants.

Method : After approval given by the Local Ethic Commitee, and written informed consent obtained, 37 ASA I-II patients, mean age 68.1 ± 9.7 years, scheduled for total hip arthroplasty, were randomly allocated in two groups : group SNP (n = 18) and group N (n = 19). After premedication (midazolam 15 mg PO), anesthesia was induced and the trachea intubated using propofol (2 mg/kg) and fentanyl (2 μg/kg). Anesthesia was maintained with the same drugs (propofol 0.2 mg/kg/min, fentanyl 2 μg/kg/h). The ulnar nerve was stimulated at the wrist with surface electrodes (trains-of-four (TOF) at 20 s intervals). An evoked compound electromyogram of the thenar area was recorded (Datex NMT monitor). Hypotension (MAP 50-60 mmHg) was induced with a SNP infusion (0.5-1.5 mg/kg/min) in group SNP and with N (3-15 mg/h) in the other group. Then atracurium was injected (0.3 mg/kg as a bolus). The average times to 25, 50, 75 and 90 % of TOF ratio recovery were compared in the two groups using ANOVA and Student t-test.

Results : The two groups were similar with regards to age, weight and hypotension level. The data summarized in fig 1 indicate that N does not extend the duration of atracurium neuromuscular block. On the contrary it appears that recovery is faster with N than with SNP.

NEOSTIGMINE ANTAGONISM OF NEUROMUSCULAR BLOCKADE INDUCED BY MIVACURIUM, VECURONIUM AND ATRACURIUM.

Boris S. Demovoi, Michel J.Baurain, Alain A.d'Hollander,
P.C.Bollen.

Anesthesiology Department, Hôpital Brugmann and Erasme,
Free University of Brussels, B-1070 Brussels, Belgium.

Introduction: Mivacurium is a new short acting nondepolarizing muscle relaxant[1] hydrolyzed by plasma cholinesterases. Since both these enzymes and the junctional acetylcholinesterase are inhibited by neostigmine[2], this study investigates and compares the neostigmine reversal of mivacurium, vecuronium and atracurium-induced paralysis.

Methods: Forty-two ASA I-II adult anesthetized (thiopental, fentanyl, N_2O) patients (with informed consent and approval by the Research Committee, Free Univ. of Brussels, Brussels, Belgium), undergoing elective surgery, were monitored (isometric adductor pollicis mechanical activity). The patients were randomly divided into 3 groups of 14 patients each and received either mivacurium (Group M: 0.15 mg.kg^{-1} followed by an infusion adjusted to maintain a 5% twitch height (TH)), either vecuronium (Group V: 100 µg.kg^{-1} and additional doses of 20 µg.kg^{-1}) or atracurium (Group A: 500 µg.kg^{-1} and additional doses of 100 µg.kg^{-1}) For reversal of paralysis, the patients received 15 µg.kg^{-1} atropine and 40 µg.kg^{-1} neostigmine when twitch tension spontaneously regained 25% of its control value. After neostigmine administration, the following variables were observed during a 15 min period: TH was measured every 10 s and train-of-four (2 Hz, TOF), every 3 min. Immediately thereafter, tetanic fades -50 and 100 Hz, 5 s duration, 1 min apart- were assessed sequentially in a random fashion. Statistical analysis of the data was performed with the Kruskal-Wallis test. The comparisons were considered significant at 0.05 level.

Results: All results are summarized in table 1. There are no significant differences between the 3 groups, for all the observed parameters.

Table 1: Evolution (%) of TOF and values (%) of TH, TF50 and TF100 15 min after neostigmine. (Mean ± Sem)(* p<0.05)

	Tof0	Tof3	Tof6	Tof9	TofF12	Tof15	TH	TF50	TF100
Miva	8±1	56±3	79±1	88±1	91±1	93±1	96±1	92±1	83±2
Vecu	7±1	68±2	78±2	82±2	85±2	87±2	94±2	93±1	82±4
Atra	8±1	55±3	78±2	86±1	90±1	92±1	98±1	90±1	78±2

Conclusions: Despite different speeds of spontaneous recovery and potential plasma cholinesterases-neostigmine interactions, the reversal obtained after neostigmine administration appears quite comparable for mivacurium, vecuronium and atracurium.

THE PHARMACOKINETICS OF ROCURONIUM IN PEDIATRIC PATIENTS: A POOLED DATA ANALYSIS

C Meistelman, P Fiset, B O'Kelly, J Frossard, B Plaud, C Ecoffey

Departments of Anaesthesiology, Hopital du Kremin-Bicêtre, Bicêtre, Institut Gustave Roussy, Villejuif, France and Mc Gill University, Montréal, Canada.

Background and goal of the study: Rocuronium is a new non depolarizing muscle relaxant with a short onset time. The aim of this study was to determine the pharmacokinetics of rocuronium in pediatric patients, particularly whether patient covariates (age, weight, height, body surface area), when added to the model, might improve the quality of the fits.

Material and methods: The study was approved by our Ethical Committee and informed consent was obtained from the parents. Twenty two ASA I or II children (3 months-) were studied. Anaesthesia was induced with N2O and halothane. After intubation without muscle relaxant, anaesthesia was maintained with N2O and an age-adjusted end-tidal concentration of halothane (1 MAC). All the patients were ventilated mechanically, when anaesthesia was stable, rocuronium 0.8 mg/kg was injected as a bolus.Venous blood samples were drawn 1, 3, 5, 10, 15, 20, 30, 60, 120, 180, 240 and 360 minutes after injection. Rocuronium plasma concentrations were determined by HPLC, the lower limit of quantification was 5 ng/ml. An extended least squares non-linear regression program (MK-Model) was used to simultaneously fit the observations for all 22 children to a single estimate of the pharmacokinetic parameters for the entire population. Patients covariates were added to the model to determine their effects. The models were analyzed by comparison of log likelihoods. If the addition of a single covariate to a parameter improved the log likelihood by > 4, then the improvment was considered statistically significant.

Results and discussion: The pharmacokinetics of rocuronium was described by a two compartment model. The inclusion of weight and age as covariates resulted in a statiscally significant improvment of the fits. The inclusion of Body Surface Area instead of weight, did not statistically improve the log lokelihood. The results are summarized in Table 1. In the proportional model, all the parameters were proportional to weight. In the age-adjusted model, only V2 and Cl1 reflected an influence of age. The absolute performance error (APE) of the model was defined as [%PE]= [100(measured-predicted)/predicted].

Conclusion: Among the covariates, the use of age or weight give the best improvment to describe rocuronium pharmacokinetic parameters in the pediatric population.

PRIMING OF ATRACURIUM WITH MAGNESIUM

E Lampl, M Dandoy

Department of Anaesthesiology, CHNO des quinze-vingts, 28 rue de Charenton, 75012 Paris, France

Background and goal of study: Magnesium potentiates depolarizing and non-depolarizing muscle relaxants (1). We studied the effect of pretreatment with magnesium sulphate ($MgSO_4$) on the neuromuscular block produced by atracurium.

Materials and methods: After approval by the human ethics committee, ASA I or II consenting patients scheduled for ophtalmic surgery were randomly allocated to two groups of 15 each. The study was double-blind. All patients were premedicated with hydroxyzine 2 $mg.kg^{-1}$ and anaesthetized with fentanyl 2 $\mu g.kg^{-1}$ followed by propofol given till loss of the eye lash reflex. After induction, patients in group A received $MgSO_4$ 0.25 $mmol.kg^{-1}$ over one min. Patients in group B received a similar volume of normal saline. Subsequently, atracurium 0.20 $mg.kg^{-1}$ was given and train-of-four (TOF) response was recorded every ten seconds using an electromyogram (Datex Relaxograph monitor).

Results: Onset time, from the end of injection to $T1<10\%$, was 137.3±21 sec in group A and 228.7±74 sec in group B ($p<0.001$). Duration of muscle relaxation, from the end of injection till T1 becomes again = 25%, was 34.6±9.2 min in group A and 26.3±8.3 min in group B ($p<0.05$). Recovery time, from $T1=25\%$ to $T1=75\%$, was 14.9±4 min in group A and 15.4±3.5 min in group B (NS). T4:T1 ratio during recovery of T1 to 25% was 23.4±10.4% in group A and 24±12.2% in group B (NS). The repercussion of $MgSO_4$ on blood pressure and heart rate (2) was insignificant.

Conclusion: In contrast to what has previously been reported for pancuronium (3), MgSO4 potentiates esentially the onset time of neuromuscular blockade by atracurium.

SUPRA-ADDITIVITY BETWEEN ATRACURIUM AND VECURONIUM

Olli A. Meretoja, Barbara W. Brandom,
Tomi Taivainen, Larisa Jalkanen

Department of Anaesthesiology, Children's Hospital
University of Helsinki, Helsinki, Finland

Background and goal of study: Supra-additivity (synergism) between some competitive neuromuscular blocking agents of different molecular structure has been observed both *in vivo* and *in vitro* [1-2]. The mechanism of supra-additivity is obscure. No study has evaluated maintenance requirement of relaxant combinations, or recovery of neuromuscular function blocked by these combinations.

Materials and methods: We evaluated three dose-ratio combinations of atracurium and vecuronium (cAV in 10:1, 4:1 and 1.6:1 in μg/μg basis) in 30 patients of 3-10 years of age during thiopentone-alfentanil-N_2O-O_2 anaesthesia. Neuromuscular block was monitored by adductor pollicis EMG. A log-probit dose-response curve of a particular cAV was created and neuromuscular block was maintained by small increments of the same cAV. Spontaneous recovery of the neuromuscular function was also recorded.

Results and discussion: An ED_{95} of a cAV in an equipotent dose-ratio (4:1 in μg:μg basis) was 95 ± 6 μg/kg of atracurium together with 24 ± 1 μg/kg of vecuronium (mean ± SEM) (figure). These dosages constituted 29% of the ED_{95} values of the parent agents and express synergism ($P < 0.0001$). cAV in nonequipotent dose-ratios also expressed synergism but was less potent ($P < 0.001$) (figure). Predominant affinity of a cAV to one α-subunit in the neuromuscular receptor explains the mechanism of supra-additivity. Hourly requirement of any cAV to maintain a 90-95% neuromuscular block was 2.0 ± 0.1 times an individual ED_{95} dose of cAV. Recovery index, time to recover from 75 to 25% neuromuscular block, was 8.9 ± 0.5 min. Both of these values are like those mirroring either atracurium or vecuronium alone. This indicates that a cAV can be regarded as an intermediate-acting neuromuscular blocking agent.

Conclusion: A cAV is supra-additive when compared to parent agents and may reduce drug consumption by 40%.

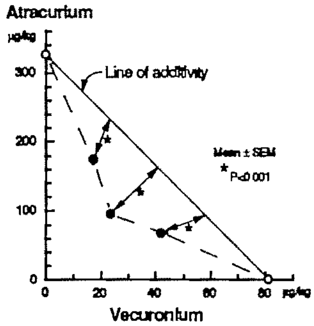

Figure. ED_{95} doses of three different dose-ratio combinations of atracurium and vecuronium (closed circles) and their parent agents (open circles). All combinations are supra-additive, synergistic.

CONCENTRATION-EFFECT RELATIONSHIP AT THE VOCAL CORDS AND THE ADDUCTOR POLLICIS FOLLOWING ROCURONIUM ADMINISTRATION

B Plaud, JH Proost, JMKH Wierda, B Debaene, J Barré,
C Meistelman,
Department of Anesthesiology, IGR, Villejuif, France
University Centre for Pharmacy, Groningen, The Netherlands
Research Group for Exp. Anesthesiology and Clinical Pharmacology, Groningen, The Netherlands
University Department of Clinical Pharmacology, Créteil, France

Background and goal of study: It was recently shown that the adductor muscles of the larynx are more resistant to nondepolarizing muscle relaxants than the muscles of the adductor pollicis (AP) (1). Several factors govern onset, and potency, but no comparative data are available on the pharmacokinetic-pharmacodynamic (PK-PD) relationship between vocal cords (VC) and the AP. The aim of the study was to determine and to compare the PK-PD relationship between the VC and the AP following rocuronium administration.

Materials and methods: The study was approved by the Local Ethical Committee and informed consent was obtained from 8 patients ASA 1-2. Anesthesia was induced and maintained with propofol and alfentanil intravenously. 500 $\mu g.kg^{-1}$ of rocuronium was injected as a infusion over 5 min. Arterial rocuronium concentrations were measured by HPLC 1, 2, 3, 4, 5, 6, 8, 10, 12, 15, 20, 30, 45, 60, 120, 180, 240, and 300 min after the start of the infusion. The lower limit of quantification of the method was 10 $ng.ml^{-1}$. Simultaneously NMB was measured at the VC and the AP after supramaximal TOF stimulation at the recurrent laryngeal nerve and the ulnar nerve. NMB of the VC was assess by pressure change in the cuff of the tracheal tube (2). Pharmacokinetic analysis and PK-PD modelling were performed using PK/PD Fit software. The transfer rate constant (k_{eo}), the half time for equilibration ($t_{1/2e}$), the plasma concentration that results in 50% paralysis (EC_{50}) and the parameter of the Hill equation (γ) were determined using the Sheiner model (3).

Results and dicussion: Results are summarized in table 1. The VC were more resistant than the AP following rocuronium administration and the rate constant k_{eo} was shorter at the VC. The greater k_{eo} at the VC than at the AP might be due to a relatively greater blood flow at the VC than at the AP muscle.

Conclusion: Following rocuronium administration the VC needs more compound to obtain the same effect and the onset of action was more rapid than at the AP.

A.142

MONITORING THE ONSET OF NEUROMUSCULAR BLOCKADE AT THE ORBICULARIS OCULI CAN PREDICT GOOD INTUBATING CONDITIONS WHEN USING 2 X ED95 OF ATRACURIUM.

B DEBAENE, C MEISTELMAN, F DONATI, A LIENHART.

Department of Anaesthesia, Hôpital Saint Antoine, Paris,
and Institut Gustave Roussy, 94805 Villejuif CEDEX
FRANCE

Background and goal of study: The onset time of neuromuscular blockade at the vocal cords and the orbicularis oculi (OO) is shorter than at the adductor pollicis (AP) (1), and intubation can be performed before maximum blockade occurs at the AP. However vocal cords are more resistant to NDMR than the AP (2). This clinical study was designed to assess if monitoring at the OO can predict good intubating conditions following atracurium.

Materials and Methods: 50 patients were studied after obtaining informed consent. Anaesthesia was induced with thiopental and fentanyl. The ulnar and facial nerves were simultaneously stimulated with train of four (TOF) every 10 sec and the muscular responses were visually recorded. Patients received either atracurium 0.5 mg.kg-1 (n = 30) or 0.3 mg.kg-1 (n = 20). In each group, intubation was randomly performed when the OO (Group OO) or the AP (Group AP) was completely blocked. Complete blockade was achieved when no response to TOF occured. In case of no complete blockade, intubation was performed 5 min after atracurium administration. Onset time (time from injection to complete blockade) was recorded for each muscle and compared using a paired t test. Intubating conditions were scored on a 1 to 4 scale (1 = excellent, 2 = good, 3 = poor, 4 = inadequate) and compared using a CHI square test. All intubations were performed by a physician unaware of the dose and the muscular responses. Results are expressed as mean ± SEM.

Results ans Discussion: After 0.5 mg.kg-1, complete blockade at the 2 muscles was achieved in all patients. Onset time at the OO was shorter than at the AP (2.35 ± 0.12 vs 3.59 ± 0.15 min respectively, $P < 0.001$). After 0.3 mg.kg-1, it was not possible to compare the onset because complete blockade was achieved only 2/20 at the OO and 12/20 at the AP. Intubating conditions were comparable in both groups: good or excellente after 0.5 mg.kg-1; poor or inadequate after 0.3 mg.kg-1 (figure).

Conclusion: When no response at the OO occur, intubation can be performed safely in all the patients. This information is provided 1.2 min before complete blockade at the AP. This monitoring cannot be useful when using small dose of atracurium because neither OO nor vocal cords are sufficiently blocked.

PREOPERATIVE CLONIDINE IMPROVES POSTOPERATIVE RENAL FUNCTION IN CABG PATIENTS

Kulka, P.J., M.Tryba, C. Menzel, F.Leurs, C.Frankenberg

Department of Anesthesiology, Intensive Care Medicine and Pain Therapy
University Hospital Bergmannsheil, Gilsingstr. 14, 4630 Bochum, Germany

Introduction: In animal studies clonidine (clo) increases urine volume, natriuresis and free water clearance which may be attributable to activation of renal α_2-adrenoceptors (1). This study was undertaken to evaluate the effect of preanesthetic clo-administration on renal function in CABG-patients.

Methods: This study was approved by the local ethical committee. 40 patients scheduled for CABG surgery randomly received 300 µg clo or placebo (pla) 1 hour prior to induction of anesthesia. Anesthesia technique and perioperative fluid therapy were standardized in both groups. For assessment of renal function creatinine clearance was determined between 6.00 p.m. and 6 a.m. the night prior to surgery (T1), after surgery (T2) and 48 hours after surgery (T3). For statistical evaluation ANOVA ($p<0.05$) was performed.

Results: Demographic parameters, duration of surgery, postoperative blood loss, fluid replacement and creatinine clearance prior to surgery (T1: pla: 94 (±25) cc/min; clo: 89 (±19) cc/min) were similar in both groups. At T2 creatinine clearance in clo-patients was significantly higher than in patients of the pla-group (pla: 63 (±17) cc/min; clo: 90 (±15) cc/min). At T3 no statistical difference between both groups could be observed (pla: 80 (±34) cc/min; clo: 90 (±33) cc/min).

Conclusion: The preoperative administration of clo (300 µg) leads to a significant improvement of postoperative renal function. Since fluid therapy was not affected by the administration of clo we hypothesize that this effect is mediated by renal α_2-adrenoceptor.

A.144

EFFECTS OF ORAL PREOPERATIVE GUANFACINE ON ANESTHETIC REQUIREMENTS.

Edgard Engelman, Maurice Lipszyc
Department of Anaesthesia, Erasme Hospital, Brussels, Belgium

Background and goal of the study: In animals, guanfacine, a potent alpha-2 agonist, produces a 100% longer sleeping time than clonidine. As an antihypertensive agent in humans, guanfacine produces less somnolence than clonidine. These conflicting results lead us to perform 2 studies to determine the effects of guanfacine on the amount of enflurane needed to maintain hemodynamic stability during carotid surgery, and on the amount of alfentanil, eventually supplemented with isoflurane, during infrarenal aortic aneurysmectomy.

Materials and methods: In each study 14 patients received 1 mg of guanfacine and 14 patients a placebo tablet in a double blind manner, 90 min. before anesthesia. For carotid surgery, anesthesia was induced with 0.2 mg/kg etomidate. After endotracheal intubation facilitated by 0.1 mg/kg pancuronium, the lungs were ventilated with an O2/N2O mixture (FiO2: 0.5). Enflurane was administered to maintain systolic blood pressure inside the usual preoperative value (baseline value) ± 20% limits. For aortic surgery anesthesia was induced by the injection of 120 mcg/kg of alfentanil and was continued by an infusion of 1.5 mcg/kg/min. To maintain the systolic blood pressure inside the baseline ± 20%, 20 mcg/kg boluses repeated at 2 min. intervals, up to 5 times, were injected; if this was insufficient to control 1 episode of hypertension, isoflurane was added in 0.2% increments. The enflurane or isoflurane concentration was measured using an infrared absorption technique. Heart rate and blood pressure were measured and stored every 5 sec using a computerized system. Plasma norepinephrine concentrations were measured during surgery in 6 guanfacine and 7 placebo patients of the alfentanil study.

Results: The distribution of the values of blood pressure, compared to the baseline values, were statistically identical between the 2 groups during both studies. In the enflurane study, heart rate was lower , and in the alfentanil study there were fewer episodes of tachycardia , in the guanfacine group.

End-tidal enflurane concentration (%) (M± SD) * = $p<0.01$

	Intubation Incision	Incision Clamping	Clamping Unclamping	Unclamping End surgery
Guanfacine	0.56±0.22*	0.71±0.21	0.54±0.13	0.81±0.18
Placebo	0.75±0.22	0.75±0.24	0.59±0.12	0.82±0.17

Alfentanil administration (mcg/kg/min) (M ± SD)

	Bolus dose	Induction Incision	Incision Clamping	Clamping Unclamping	Unclamping End surgery
Guanfacine	117±7.9	3.9±2.9	6.9±4.2	2.6±1.2	3.3±2.2
Placebo	120±2.7	2.8±1.7	5.6±2.3	1.9±1.0	2.8±1.8

There was no statistical difference in the amount of anesthetics administered during surgery between the 2 groups in both studies. The amounts of isoflurane supplementing alfentanil were also identical. Norepinephrine concentrations were lower ($p=0.02$) in the guanfacine group.

Conclusions: This lack of sparing effect could be due to the a2-C10 selectivity of guanfacine, an a2-C4 isoreceptor activity seeming necessary to express an anesthetic-like action.

A.145

PHARMACOKINETICS AND EFFECTS OF I.M. ALFENTANIL AS PREMEDICATION FOR OUTPATIENT CATARACT SURGERY

Timo Ali-Melkkilä, Markku Virkkilä, Helena Soini, Jussi Kanto.
Department of Anaesthesiology, University of Turku and Analytic department, Orion Pharmaceutica. Finland.

Background and goal of study: Although not routinely used in outpatients cataract surgery, a preanaesthetic medication may be useful to some patients, because it alleviates the anxiety and pain associated with the periocular injection of the local anaesthetic. Alfentanil has been shown to reduce pain from 5 to 60 min after i.m. injection and may thus be suitable premedication for short painful procedures, such as periocular block. The goal of the present study was to determine the basic pharmacokinetic features and clinical effects of alfentanil, when injected into the deltoid (D) or gluteal (G) muscle as premedication of periocular anaesthesia in outpatient cataract surgery.

Material and methods: After a written informed consent 90 patients scheduled for outpatient cataract surgery with regional anaesthesia were included in this randomized, placebo-controlled double-blind study. Alfentanil (12.5 μg/kg), injected into the deltoid(n=30) or gluteal(n=30) muscle 15 min before the periocular block was compared with placebo(n=30). The plasma concentrations of alfentanil were analyzed with capillary gas chromatography. In addition to heart rate, blood pressure and oxygen saturation, subjective anxiety, sedation, nausea and pain were assessed with a visual analogue scale.

Results and discussion: In the deltoid group the mean alfentanil concentrations were significantly higher and the mean peak plasma concentrations were achieved more rapidly (table). Only alfentanil injected into the deltoid muscle was able to reduce the pain associated with the periocular block. A mild sedative effect was found in both the groups.

Conclusion: We conclude that sufficient pain relief for periocular block can be achieved with alfentanil injected into deltoid muscle. The deltoid alfentanil had a short duration of action and was not associated with any clinically significant side-effects.

Table: pharmacokinetic data

PHARMACOKINETIC BEHAVIOUR OF TRANSDERMAL FENTANYL

Martine Van Bastelaere, Georges Rolly, Achiel Van Peer*
Department of Anaesthesiology, University of Ghent, Ghent, Belgium
*Janssen Pharmaceutica, Beerse, Belgium

This study reports the pharmacokinetic behaviour of transdermally applied fentanyl in 20 patients, out of a group of 40, who were randomly assigned to receive double-blind transdermal fentanyl (75 μg/h) or placebo.

Patients and methods: after approval by the Ethics Committee 40 ASA I or II informed patients, selected for major orthopaedic surgery, were studied. After 10 mg diazepam orally 120' before anaesthesia, the transdermal patch was applied. Anaesthesia consisted of propofol, small boli of alfentanil or sufentanil, vecuronium, N_2O/O_2 and isoflurane. After surgery if the patient complained of pain, morphine was given (2 mg I.V. in the recovery room and 5 mg I.M. on the ward). Plasma fentanyl levels were measured at regular intervals by RIA method (detection limit 0.1 ng/ml).

Results: after opening the code the 20 patients, receiving fentanyl, had the following gender distribution: 13 males, 7 females. The mean (±SD) age and weight were: 42.6(±13.9) y and 75.0 (±10.6) kg. The fentanyl plasma concentrations (ng/ml) are shown in table. The maximum observed concentration (Cmax) was 1.63(±0.53) ng/ml, at 32.4 (±16.1) h after application of the patch. The mean fentanyl concentration during the plateau phase was 1.31 (±0.40) ng/ml. The area under the curve was: AUC_{0-96h} 91.3(±32.8) ng.h/ml and $AUC_{0-\infty}$ 100(±37) ng.h/ml. The elimination half-life of fentanyl after removal of the patch was 16.9(±4.8) h and the elimination rate constant 0.045 (±0.015) 1/h. The clearance was 1023 (±380) ml/min.

Discussion: the attainment of useful fentanyl concentrations after transdermal application is rather slow, but after 12 h, the concentrations were fairly stable, but with wide inter-individual variations (0.84-2.95 ng/ml). The elimination half-life of transdermal fentanyl is almost 4 times larger than after I.V. administration.

A.147

SUFENTANIL FIRST-PASS PULMONARY UPTAKE AT THREE DIFFERENT STEADY STATE CONCENTRATIONS OF THE DRUG

Fred Boer, Frank Engbers, Toine Burm, James Bovill, Adrie Hak.

Department of Anaesthesiology, University Hospital Leiden, Leiden, The Netherlands.

Background and goal of the study. Sufentanil undergoes significant first-pass pulmonary uptake in spontaneously breathing patients[1]. Pulmonary uptake could be affected by saturation of binding in the lungs. We have investigated the effect of increasing steady state background concentrations of sufentanil on the pulmonary uptake of the drug.

Materials and methods. Ten patients scheduled for elective coronary artery surgery were studied. Patients had good left ventricular and pulmonary function. Anaesthesia was given with a computer controlled, pharmacokinetic model based infusion of sufentanil. Predicted plasma concentration for intubation of the trachea was 9 ng ml^{-1}, after which the predicted concentration was allowed to decrease to 4 ng ml^{-1}. Pulmonary uptake of sufentanil was studied during predicted plasma concentrations of 4, 8 and 16 ng ml^{-1}. During each study period indocyanine green 16.7 mg and sufentanil 65 μg was injected in 1 s via the atrial port of the pulmonary artery catheter. With a fraction collector arterial blood samples were collected at 1 s intervals for 60 s after drug injection. In each sample the indocyanine green and sufentanil concentrations were measured. Pulmonary retention ratio of sufentanil was calculated using a standard formula.

Results Measured background concentrations were 2.8 (0.66) (mean (SD)), 6.9 (1.2) and 15.9 (2.6) ng ml^{-1}. First-pass pulmonary retention of sufentanil was not affected by increasing background concentrations of the drug. First-pass retention for the 3 background concentrations was 67.6 (7.1)%, 64.7 (6.9)% and 59.9 (11.0)% respectively.

Conclusion. Sufentanil first-pass pulmonary retention is unaffected by increasing background concentrations of the drug. In the concentrations used there is no evidence of saturation of pulmonary binding sites for sufentanil.

COMPUTER-CONTROLLED SYRINGE PUMP IMPROVES SAFETY OF PHARMACOKINETIC MODELS

DURANTEAU R., GUESDE R., RIOU B., DERIAZ H., VIARS P.
Dpt of Anesthesiology, CHU Pitié-Salpétrière, Paris, France.

Goal of study : Timing and volumetric accuracy are a prerequisite in computer-controlled intravenous (iv) infusion. Pharmacokinetic models have been described. They are "ideal" since few mention the reliability of all components : tubing, syringe, data link, computer. No real component is as defect-free as automated iv delivering systems should be. A program was developped to evaluate their incidence.

Materials and Methods : The equipment consisted of tubings, stop-cocks, a syringe pump, an RS 232 link, and a "driving" computer (PC), which run a C program. A mains/battery powered syringe pump was selected (Pilot C, Becton-Dickinson). Available flow rates ranged from 0.1 to 120.1 ml/h in 0.1 ml/h increments, with an additionnal 800 ml/h bolus. When driven by a computer, any data link failure halted the pump. Back-pressure was monitored. No patient was present since incidents were tested.

Results and discussion : Numerous events randomly interfered with the infusion process and added complexity to the system. Some were detected by the program : tubing occlusion, unclamped or empty syringe, line disconnection, time lag between a command and its execution, signal interference, battery discharge. Others had to be keyed in : drug identification, tubing leak. All events had to be monitored, evaluated, and appropriate actions done, without undue "crashing" of the pharmacokinetic model. The maximal infusion rate of the pump was somewhat too low to perform a rapid-sequence induction, unless the syringe was hand-actuated (secured in the pump clamp). Backlash in drive mechanisms has been studied by several authors, but was not included, unless an occlusion occured. Several programming techniques were considered for the driving computer : (1) *Artificial intelligence techniques* are accurate, but are complex, somewhat expensive, and not fast enough when run on today's "personnal computers". (2) *Fuzzy-logic techniques* are simple, require minimal modeling, but do not bring reproducible analytic solutions and sacrifice precision. (3) *Finite-state machines* are inherently accurate, but rely on a deep analysis of the hanshaking protocols chosen by pump makers. We choosed them to handle illegal states and transitions.

Conclusions : Many pumps implement simple computer protocols which suit ideal conditions, but real practice calls for fully-controllable devices, with safer protocols. Reliable finite-state machines can provide a cost-effective front-end to complement ideal pharmacokinetic models.

A.149

TARGET-CONTROLLED INTRAVENOUS SEDATION WITH PROPOFOL

Carine Mergaert, Georges Rolly and Linda Versichelen

Department of Anaesthesiology, University of Ghent, Ghent, Belgium

Patients and methods: a group of ten ASA I or II patients, who received locoregional anaesthesia for lower limb orthopaedic surgery, were included in this study. Epidural anaesthesia involving L3-L4 and L5 roots was performed with lidocaine 2 % plain. After successful sensory block each patient received intravenous sedation with propofol 1 %. A not yet marketed computer controlled infusion pump (Ohmeda), with a program developed by Dr Kenny, was used. A target bloodconcentration of 2 µg/ml of propofol was programmed on the pump for the whole procedure. Following assessments were made: ECG, noninvasive bloodpressure, SpO_2. An anaesthesia brain monitor (Datex) was used to assess the effect of sedation: SEMG (spontaneous electromyogram) of the frontal muscle and EEG (zero crossing frequency and mean integrated voltage) were continuously followed and graphically recorded. Bloodsamples were taken at fixed moments: at the start (To), after 15, 30 and 60 min., at the end of infusion and awake. The concentrations were measured by R.I.A.

Results: the mean (±SD) age and weight were: 49(±19) y and 61.3(±11.4) kg. All but 2 patients had a satisfactory sedation (Ramsay Score 2-3). After a computer controlled initial bolus dose (2.9 ± 0.5 ml), a statistically significant decrease of the SEMG value (50 U ⟶ 20-30 U) was noticed and these low values were observed during the whole procedure. ZXF and MIV remained stable. The propofol bloodconcentrations are shown in table. At each time period they were lower ($p<0.05$) than predicted. SEMG values returned to normal within ± 3 minutes after ending the infusion.

Conclusion: in the low dosage range the computer controlled infusion system overestimates real propofol bloodconcentrations but induces satisfactory sedation.

DETERMINATION OF A PHARMACOKINETIC MODEL FOR PROPOFOL INDUCTION OF ANAESTHESIA

Xavier Viviand, Catherine Guidon-Attali, Bruno Lacarelle, Claude Martin, Georges François.

Hôpital Nord and Hôpital La Timone -Marseille - France

Background and goal of study : the pharmacokinetic properties of propofol (P) make it particularly suitable for computer-assisted total intravenous anesthesia (CATIA). For short-term infusion, the pharmacokinetic model of Gepts (GPM) is suitable: bias of -2.2% and precision of 19.8% (1). The aim of this study was to evaluate the performance of this model during the first minutes of infusion : induction of anaesthesia.

Materials and methods : 10 patients, 6 men, 4 women (mean age: 52±14, range: 33-72 years, mean weight:61±16, range: 47-86 kg), scheduled for colonoscopy, were included after institutional approval and informed consent. A computer controlled an Ivac 560 volumetric pump. During anaesthesia, the patients spontaneously were breathing an oxygen-air mixture. The infusion scheme was 20 mg.kg-1 for 5 min, followed by 9 mg.kg-1 for 30min and finally 6 mg.kg-1 until 50th min. Venous blood samples were taken before and 4.5, 10, 20, 34 and 50 min after the beginning of infusion. Actual P concentrations were measured by HPLC. The determination of PM was made by weighted non-linear regression analysis. Bias was estimated by the Median Performance Error (MDPE) and precision by the Median Absolute Performance Error (MDAPE).

Results and discussion : at time 4.5 min, the GPM showed a significant bias (MDPE) : -94 % from zero ($p < 0.01$) and precision (MDAPE) was only 40 %. The calculated pharmacokinetic parameters are showed in the table. Compared to GPM, the volume of the central compartment V1 is dramaticaly higher (32 vs 16.9 L) but the value of K10 is not very different (0.146 vs 0.1190 min-1).

Conclusion : the GPM presented a poor performance to estimate blood concentrations of P during induction. The new pharmacokinetic parameters presented here seem more adequate but require further investigations to be validated.

	Median	Coefficient of Variation
V1 (L)	32	24 %
K10 (min-1)	0.146	18 %
K12 (min-1)	0.045	42 %
K21(min-1)	0.008	170 %

A.151

PHARMACOKINETICS OF PROPOFOL AND ITS CONJUGATES AFTER CONTINUOUS INFUSION IN NORMAL AND RENAL FAILURE PATIENTS

N.NATHAN, J. DEBORD*, F. NARCISSE,
J.L. DUPUIS, G. LACHATRE*, P. FEISS.
Dept of Anaesthesiology, * Dept of Pharmacology,
LIMOGES FRANCE.

Propofol, 2-6 diisopropyl phenol, a short-acting hypnotic, chiefly metabolized by liver, has none effect on renal function. Its pharmacokinetics in end-stage renal failure patients is only known after bolus infusion. The aim of this study was to determine the pharmacokinetics of propofol and its conjugates after continuous infusion in end-stage renal failure patients as compared to normal

Methods : After approval of the ethical committee and informed consent of the patients, 6 end-stage renal failure patients (group A) and 5 ASA I patients (group B) were included in this study. Patients with cardiac or hepatic abnormalities were excluded. None premedication was done. Anesthesia was induced with propofol (2 $mg.kg^{-1}$ and 2.5 $mg.kg^{-1}$, group A and B respectively) and fentanyl (0 1 mg) then maintained with propofol (9 $mg.kg^{-1}$ and 10 $mg.kg^{-1}$, group A and B respectively) and bolus of 0.1 mg fentanyl when appropriate. Plasma propofol concentrations were determined at various intervals during infusion and during 24 H after its end by HPLC with electrochemical detection. Plasma concentration of propofol glucuronide and of other conjugates were measured after previous action of a Bèta-glucuronidase or acid hydrolysis. Preliminary estimates of the parameters were obtained by the peeling method. The number of exponentials was determined by inspection of experimental plots and computed curves, convergence of the minimization procedure and inspection of the normalized residuals. Pharmacokinetic results were expressed as median and range because of the large variability of results and compared with Man Withney-U-test.

Results : Patients were not different between groups as regard to age, sex, weight, lenght of anaesthesia and total dose of propofol (not shown). Pharmacokinetic parameters of plasma propofol are reported in table 1. The large variability of results was due to patient 1 and 5 who presented a smaller clairance and a longer last half-life. These two patients were not different from other patients as regard to demographic or biological data. The results in patient 1 might be explained by a longer sampling period (48 H). In patient 5, propofol infusion was reduced by a half because of a severe decrease of arterial pressure. Meanwhile the times of eyes opening to verbal command were not different between groups. Propofol glucuronide pharmacokinetics were not different between groups whereas the other conjugates accumulated in blood of renal failure patients (not shown).

Conclusion : The change of volume of distribution at steady state in end stage renal failure patients remained without clinical significance. Nevertheless because of high interpatient variability, accumulation of propofol might be observed after long time infusion as may occur in intensive care unit. The effects of the metabolites accumulation on drug-drug interaction deserves to be evaluated in such patients.

Table 1 : Pharmacokinetics of propofol. Median (range). * $p < 0.05$.

	Group A (n=6)	Group B (n=5)
T 1/2 α (min)	0.09 (0.44)	0.03 (n=1)

PROPOFOL (2,6 DIISOPROPYLPHENOL) AS AN ANTIOXIDANT IN-VITRO: A DOSE RESPONSE STUDY

Sean Bennett, Vivienne Nelson and Terence Green
Department of Cardiothoracic Anaesthesia and Surgery,
University of Umeå, Umeå, Sweden.

Introduction: Recent work suggests propofol may have a role as an antioxidant in-vitro[1]. Also, propofol, in rat liver tissue in sufficient concentration to cause anaesthesia, has been shown to inhibit lipid peroxidation initiated by a Fenton-type free radical generating system[2]. The aim of this study was to determine the ability of propofol, at different concentrations, to inhibit organo-radicals. Diprivan (commercial propofol in intralipid) and butylated hydroxytoluene (BHT- a free radical scavenger, chemically similar to propofol) were controls.

Method: Riboflavin in EDTA/phosphate buffer was chosen as the free radical generating system as it is known to produce superoxide and organo-radicals when exposed to ultraviolet (UV) light. This system was placed in the reaction chamber of an oxygen analyzer, with a Clark electrode to measure the O_2 tension in solution. Serial dilutions of; propofol, diprivan/intralipid or BHT were then added to the chamber. The reaction chamber was illuminated with UV and the observed fall in O_2 tension was drawn on a chart recorder indicating free radical generation. The experiment was repeated with the addition superoxide dismutase (SOD).

Results: A clear dose/response curve for propofol demonstrated its ability to reduce O_2 uptake (Fig). This was not seen with diprivan or BHT. The addition of SOD allows the organo-radical component to be seen.

Discussion: The effect on O_2 uptake seen with propofol, especially in the presence of SOD which eliminates the superoxide component of O_2 uptake, supports the view that propofol's antioxidant properties are directed towards the organo-radicals rather than superoxide and hydroxyl radicals. Whether this occurs and/or its significance at clinical doses has yet to be determined.

A.153

PROPOFOL ANAESTHESIA WITH SPONTANEOUS BREATHING FOR EXTRA-CORPOREAL SHOCK WAVE LITHOTRIPSY

Thomas Pasch, Tamara Hawelski

Institute of Anaesthesiology,
University Hospital, Zurich, Switzerland

Background and study aims. Initial claims of "anaesthesia-free" lithotripsy with the 2nd generation HM3 Dornier machine resulted in prolongation of procedures, and often incomplete disintegration of stones. On the other hand, since conventional general or regional anaesthesia appeared exaggerated, we introduced a technique based on an analgesic-supplemented propofol infusion, that preserved spontaneous breathing. This clinical study was aimed at assessing the practicability, ease of use, and safety of this technique during ESWL.

Material and methods. The study involved 99 patients. After premedication with pethidine (1 mg/kg i.m.) a transcutaneous PCO_2 ($PtcCO_2$) electrode (Roche) was applied to the skin of the upper thorax. After stabilization an arterial blood gas analysis was performed and the patient positioned. Further parameters monitored included ECG, oscillometric blood pressure (BP), and pulse oximetry (Oxyshuttle, Sensormedics). During localization of the stones, patients received either 20 µg fentanyl (n = 48) or 0.2 mg alfentanil (n= 51) and 4 l O_2/min were administered via a nasal tube. Anaesthesia was then induced by infusion of propofol (0.4-2.5 g/h). During the procedure, the maintenance infusion rate of propofol, supplements of analgesics and nasal O_2 flow were adjusted to meet individual needs.

Results. Onset of and recovery from, anaesthesia were rapid. There was a close linear correlation between $PaCO_2$ and $PtcCO_2$ (r=0.923). Arterial O_2 saturation (SpO_2) was stable while mean nasal O_2 flow had to be increased to 5.3±1.5 l/min. $PtcCO_2$ was 4.9±0,6 kPa before induction and increased to 6.3±0.8 kPa after 30 min. In all patients it was necessary to support the jaw (chin-lift) to keep the upper airways open. Mean BP decreased by 10-20 %, and the heart rate by 3-8 % during propofol anaesthesia. Acceptance by patients and urologists was excellent.

Conclusion. Continuous infusion of propofol is a safe and easily feasible anaesthesia technique for mildly to moderately-painful procedures. The degree of hypoventilation is clinically acceptable and oxygenation is preserved if the airways are kept open and O_2 is supplemented.

A.154

Quality of Induction: A Clinical Comparison of Etomidat-Lipuro^R and Hypnomidate^R

Wiebalck A[*], Vanacker B, Van Aken H, Sermeus L, Bouillon R[**], Amery A[***]
Department of Anesthesiology, University Hospitals, Katholieke Universiteit Leuven, Belgium

Goal: The purpose of this study was to compare etomidate in a lipid emulsion (Etomidat-Lipuro^R; Braun, Melsungen) and etomidate in propylene glycol (Hypnomidate^R; Janssen Pharmaceutica) in 110 patients in terms of anesthetic induction characteristics with special references to injection side effects, hemodynamic changes and the quality of induction.

Materials and Methods: In the first part of it, 110 patients were assigned at random to two groups in which induction of anesthesia was performed either with Etomidat-Lipuro^R or Hypnomidate^R. Anesthesia was started by iv injection of 25 µg/kg Alfentanil (Rapifen^R, Janssen Pharmaceutica). One minute later, the hypnoticum was injected in a well running intravenous line (18 G cannula). This cannula was used only for the hypnoticum and removed 15 minutes later. During injection the patients were asked to inform the anesthesiologist spontaneously and on request about the sensations at the injection place. The time from the beginning of anesthesia until the disappearance of the eyelash reflex was measured. Myocloni were documented. The patients were ventilated and vecuronium was administered to allow good intubation conditions 2 - 3 minutes later. For the first 10 minutes, blood pressure and heart rate were measured every minute. Postoperatively it was always the same investigator who made the rounds once a day and looked after the injection sites. Signs of pain, redness, swelling, induration, thrombophlebitis or thrombosis were noted.

Results and Discussion: The loss of the eyelash reflex was 42,9±8,7 s versus 42,2±11,0 s after the administration of Etomidat-Lipuro^R and Hypnomidate^R.respectively. Myocloni occurred in almost 50%, most times slightly, evenly distributed over both groups. The hemodynamic changes were minimal in both groups. After administration of Alfentanil^R, local side effects of the hypnotics were scarce with a tendency to being even weaker and more seldom in Etomidat-Lipuro^R group (3/55 versus 8/55). The postoperative vein reactions were generally mild and occurred in 17 out of 55 patients after Etomidat-Lipuro^R and in 15 out of 55 patients after Hypnomidate^R. In most cases these signs were no longer present on the second day after the procedure.

Conclusion: Alfentanil reduces the injection pain of etomidate induction agents. Local side effects are minimal after the administration of both products.

MIDAZOLAM PREMEDICATION: A FORENSIC APPROACH TO PHARMACOKINETICS AND AMNESIA

Motsch J, Baller S, Bach A, Aderjan R*, Martin E

Dept. of Anesthesia, * Dept. of Forensic Medicine
University of Heidelberg, Germany

Background: Midazolam is used frequently for premedication because of its amnesic and anxiolytic effects. Benzodiazepine abuse and intoxication are frequent, and midazolam's amnesic properties are of great interest in forensic medicine. Therefore, we studied first whether the intake time and intake dose of oral midazolam can be determined by measuring the plasma level of midazolam and its 1-hydroxy-metabolite and second, whether anterograde amnesia after midazolam intake is dose dependent.

Material and methods: After institutional approval 20 patients scheduled for elective surgery were randomly allocated to receive either midazolam 7.5 mg or 15 mg for per os premedication. Blood samples were drawn at 0, 30, 60, 120, 180, 240, 360 and 720 minutes after midazolam intake. For assessment of amnesia a modified picture test was used. Plasma levels of midazolam and 1-hydroxy-midazolam were measured by gaschromatography (C. Erba Instr. GL6000 with ^{63}NiECD and a HP 3396 series II integrator).

Results and discussion: The expected metabolite 1-hydroxy-midazolam was not traceable using gaschromatography with a sensitivity limit of 5ng/ml. Maximum plasma levels of 6.4 ± 4.6 ng/ml midazolam (mean ± SD) were found at 30 minutes after intake (sensitivity limit of 1ng/ml). Unrelated to the intake dose plasma levels showed a striking variability. No patient showed anterograde amnesia in the picture test. No correlation between intake dose and test result could be demonstrated. Higher plasma levels of midazolam and 1-hydroxy-midazolam as reported by others could not be confirmed in this study.

Conclusion: Premedication with midazolam p.o. does not lead to anterograde amnesia. Analysis of the plasma level of midazolam and metabolites does not allow the extrapolation to the time of intake or the minimal oral dose taken due to the variability in metabolism.

DOSE DEPENDENT EFFECTS OF ORAL MEDICATION WITH MIDAZOLAM

Peter Biro, Eli Alon, Gabriele Weidmann, Sabine Pietzsch

Department of Anaesthesiology, University Hospital,
Zurich, Switzerland

Introduction: The aim of the study was to examine the psychological effects, well-being and side-effects after various doses of oral midazolam medication.

Methods: The study protocol was approved by the Ethical Committee of the University Hospital of Zurich. After informed consent was obtained, 80 adult patients in the ASA physical status I and II were randomly assigned to one of five different medication groups: 3.75 mg, 7.5 mg, 11.25 mg, 15 mg midazolam, placebo. The medication was given in a double-blind fashion 60 min before induction of general anaesthesia for various surgical procedures. At 3 definite stages (before medication, 30 and 60 min after medication), blood pressure, heart rate, transcutaneous O_2-saturation and respiratory rate were measured. Sedation and well-being were graded according to a 5-point scale, subjective fear level by visual analogue scale, concentration by standard psychometric tests. Anterograde and retrograde amnesia were measured by auditive and optic tests. Finally, patients were asked whether in case of future surgery they would prefer the same or a different medication.

Results: Demographic data were similar in all groups. There was no significant difference in respiratory rate, O_2-saturation, blood pressure or heart rate. Alertness declined slightly after 30 min in all groups; this decline was accentuated after 60 min in the groups treated with 7.5 and more mg midazolam. Decline in concentration ability was analogue to the trend in alertness. During the entire measuring period anxiolyse was in all midazolam groups not different from placebo. All midazolam groups showed a significant dose dependent amnesia compared with placebo. Subjective well-being scores showed no differences between the groups. All groups indicated a wish for the same medication in the future. Only few side-effects were seen following doses of 7.5 mg and higher, and included ptosis, strabismus, speech disorders, disorientation, and vertigo.

Conclusions: Midazolam administered orally prior to surgical procedures showed a marked inter individual variability. Sedation, decline of concentration-ability and amnesia were dose dependent and were evaluated by the patients as acceptable. Anxiolyse was not significantly different from placebo. The dose of 7.5 mg midazolam showed the best relation between desirable and undesirable effects. Adequate attention given to the patient by the anaesthesiologist prior to surgery seemed to be as important and beneficial as the oral medication.

A.157

FLUMAZENIL FACILITATES INTRAOPERATIVE AROUSAL IN SCOLIOSIS SURGERY.

Zbigniew Jerry Koscielniak-Nielsen, Jens Schierbeck,
Hanne Lisbeth Stens Pedersen, Grazyna Perko.

Department of Anaesthesia, Rigshospitalet, University
of Copenhagen, Denmark.

Background and goal of study: Early warning of spinal cord damage during scoliosis surgery is desirable to avoid permanent neurological deficit. Therefore, patients are awakened intraoperatively and instructed to move both feet on command (wake-up test) [1]. Flumazenil speeds up recovery from anaesthesia. It does not affect analgesia, which makes it suitable for arousal during extensive spinal surgery. The potential disadvantage of flumazenil is the antagonism of amnestic and anxiolytic action of benzodiazepines. This study was designed to compare speed and quality of intra-, and postoperative arousal with or without flumazenil during midazolam, fentanyl, N_2O/O_2, atracurium anaesthesia. Recovery and amnesia were also assessed.

Materials and methods: 24 adolescents with scoliosis, undergoing extensive posterior fusion of thoraco-lumbal spine, completed this randomized, double-blind, placebo controlled study. At the surgeons request the absence of neuromuscular block was ensured. N_2O was disconnected, flumazenil or 0.9% NaCl were injected in refracted doses. Patient was repeteadly instructed to move hands and feet. After the operation instructions were repeated, and the patient was requested to give full name and the date of birth.

Results and discussion: Intraoperative motor response times (median ± range) were 2.5 min (1.0-5.2) after flumazenil and 8.0 min (1.7-28.5) after placebo, (P=0.02). Five patients in the placebo group did not wake up within 10 min and received naloxone. The quality of arousal was similar in both groups. Two youngest patients (one in each group) woke up violently and needed physical restrain to avoid injury. Postoperative motor response times were 12.0 min (5-42) in the flumazenil group and 15.2 min (4-40) in the placebo group (NS). Recovery times were 27.5 min (7-415) after flumazenil and 25.0 min (8-160) after placebo (NS). Two patients (one in each group) recalled intraoperative test but had no unpleasant memories.

Conclusions: Flumazenil facilitates the intraoperative arousal during scoliosis surgery under midazolam, fentanyl, atracurium, N_2O/O_2 anaesthesia. It helps to avoid reversal of analgesia. It does not facilitate postoperative motor testing, recovery, nor does it affect recall of the intraoperative events.

USE OF THORACIC EPIDURAL BLOCK FOR PERIOPERATIVE ANALGESIA IN CHILDREN

A H Entress, S P S Cheema

Killingbeck Hospital, York Road,
Leeds LS14 6UQ, Yorkshire, England

Although lumbar and caudal epidural analgesia is well recognised in children, there has been relatively little written about the feasibility of thoracic epidural block in infants and children mainly due to worries concerning the technical feasibility of providing such a service. Here we would like to present 11 cases of thoracic epidural block in infants and children weighing from 6 - 21kg using 0.25% Bupivicaine.

The epidural space was identified using loss of resistance at T5/6 with a 19 gauge Tuohy needle with either midline or paramedian approach and a catheter inserted for maintenance of analgesia post operatively. The initial dose of Bupivicaine was 0.3ml per kg with an infusion rate of 0.1 - 0.2ml per kg per hour post operatively.

No difficulties were experienced in inserting any of the thoracic epidurals and there was total cardiovascular stability in all cases. All cases were extubated in theatre and quality of analgesia was judged by medical and nursing staff to be excellent in all cases in the post operative period.

It was felt to be especially beneficial in cases of coarctation and due to the lack of post operative hypertension often seen in these cases, we see no reason why this technique should not be employed routinely in experienced hands to provide perioperative analgesia in all suitable cases. We are currently further evaluating the technique using thermal imaging to evaluate the extent of the block.

Results

Age (Mths)	Weight (Kg)	Operation
34	12	Coarctation
61	15	Coarctation
41	12	Empyema
63	20	Coarctation
20	12	Central Shunt
8	6	Central Shunt
62	18	Removal of pacemaker
24	12	Division of vascular ring
18	12	Coarctation
19	8	Lobectomy
8 yrs	21	Lobectomy

BLENDED ANAESTHESIA IN MAJOR PAEDIATRIC SURGERY - TOP-UP VS CONTINUOUS EPIDURAL INFUSION

G Savoia, F Lucke*, G Scermino *, B Sparacia, A Sansone

Department of Anaesthesia and Intensive Care, Palermo and Napoli* Medical Schools, Italy

Background and goal of study: Blended anaesthetic techniques include general anaesthesia for induction, maintenance of hypnosis, muscle relaxation, and loco-regional anaesthesia for analgesia and neurovegetative reflex supression. The aim was to compare two blended anaesthetic techniques using either continuous or intermittent epidural administration of bupivacaine in paediatric patients undergoing major thoraco-abdominal surgery.

Materials and methods: 40 children (3-12 years) were allocated to two groups. Group A received a continuous epidural infusion of bupivacaine 0.25% at 0.2 ml/kg/h after a bolus dose of 0.3 ml/kg during surgery follwed postoperatively by an infusion of bupivacaine 0.125% at 0.2 ml/kg/h combined with buprenorphine at 6 mcg/kg/24h. Group B received the same induction dose of buipivacaine followed intraoperatively by bolus doses of 0.2 ml/kg as needed. Postoperatively, children in group B received buprenorphine 2 mcs/kg as needed. Both groups had the same premedication (buprenorphine 3 mcg/kg + atropine 10 mcg/kg), induction (propofol 3 mg/kg), maintenance of anaesthesia (propofol 6 mg/kg/h) and muscle relaxation (atracurium 500 mcg/kg/h). Intraoperative haemodynamic instability (mean blood pressure and/or heart rate differing more than 20% from awake), insufficient depth of anaesthesia, postoperative desaturation ($SpO2<90\%$), cooperation during postoperative physiotherapy and VAS integrated score (0-10 hourly VAS score x 24h), and words more frequently used, chosen from a paediatric short form questionary (1) were recorded. The Chi-square and T-tests were used for the statistical analyses. A $p\text{-value}<0.05$ was considered significant.

Results: The main advantages of the continuous epidural technique (group A) were better haemodynamic stability ($p<0.05$), fewer children with insufficient anaesthetic depth ($p<0.05$), better cooperation during postoperative physiotherapy ($p<0.05$) and less pain ($p<0.05$).

Conclusion: Blended anaesthesia with propofol, atracurium and continuous infusion of bupivacaine at 0.25% and buprenorphine is highly recommended for the perioperative anaesthetic management of children undergoing major surgery.

A.160

CLONIDINE IN PAEDIATRIC CAUDAL ANAESTHESIA

Samir Jamali, Sylvaine Monin, Christian Begon,
Anne-Marie Dubousset, Claude Ecoffey

Département d'Anesthésie - Réanimation, Université Paris-Sud, Hôpital de Bicêtre, 94275 - Le Kremlin-Bicêtre, FRANCE

Background and goal of the study : Caudal anaesthesia was a reliable, widely used and safe technique in children. Clonidine, epidurally administered , was found to increase moderately the duration of postoperative analgesia in adults (1), it was never studied in children to our knowledge.
Material and methods : After obtaining approval of the ethics committee and a written informed consent , 22 children aged 1-7 yrs were randomized in a double-blind manner in 2 groups. After induction with halothane or thiopentone, they were all intubated with or without muscle relaxants, and a caudal anaesthesia was performed with 1ml/kg of 0.25 % bupivacaine (maximum 20 ml). Epinephrine 1/200 000 was added in group EG, or 1 µg/kg of clonidine in group CG. Anaesthesia was maintained with halothane or isoflurane only, no opioids were injected. After extubation, vital signs and haemodynamic parameters (systolic arterial pressure SAP, heart rate HR, respiratory rate RR, SpO2) were monitored every 5 min for 3 hours, then every hour for 24 hours (SAP, HR). The analgesic effect was evaluated every hour with the Broadman's (2) "objective pain-discomfort scale" (BS) until the first administration of an analgesic, which was based on pain signs, or complaint of pain in elder children. The number of analgesic administrations during the first 24 hours (AA) was recorded. Data was evaluated for statistical analysis using ANOVA tests. A Chi-square was used to compare AA and a Mann-Whitney test for BS.
Results and discussion : The two groups were identical for age (48 ± 24 vs 43 ± 23 months) (mean ± SD, respectively in group EG and group CG), weight (16.6 ± 4.7 vs 14.9 ± 3.9 kg), duration of the surgery (58 ± 48 vs 53 ± 36 min), SAP (95 ± 8 vs 98 ± 6 mmHg), and HR (115 ± 23 vs 114 ± 23 bpm). No difference was found between groups in the minimum RR (26 ± 5 vs 22 ± 3 /min with minimum values of 19 vs 17), or minimum SpO2 (97 ± 1 vs 97 ± 1 with minimum values of 95 vs 94). SAP was significantly lower in CG all over the 2 first hours after the caudal anaesthesia ($p < 0.05$), with no clinically difference (maximal mean drop was 6.5 % in CG after one hour). No bradycardia was recorded. The duration of analgesia was longer in CG (table). The maximal BS at the moment of the first analgesic administration was higher in EG (3.4 ± 1.4 vs 2.0 ± 1.2, $p < 0.05$). AA was higher in EG (2 ± 1 vs 1 ± 1, $p < 0.01$).
Conclusion : We conclude that the addition of 1 µg/kg of clonidine to the caudal anaesthesia in children is an efficacious method for the prolongation of postoperative analgesia. However, more investigation is recommended for evaluation of the side effects.

Clonidine group	1009 ± 566 min *	130 min - 24 h

A.161

PROPOFOL FOR TRACHEAL INTUBATION IN PAEDIATRIC OUTPATIENT ANAESTHESIA

By : AMR MAHMOUD MONTASSER, M.D., F.R.C. Anaes. (England).
Chairman of the Anaesthesia Department, Research Institute of Ophthalmology, Giza, Egypt, Medical Director of Shaalan Surgicenter, Giza, Egypt

Background & Goal of study : Tracheal intubation is indicated in many paediatric outpatient surgical procedures. It can be achieved by deep inhalational anaesthesia or an I.V. anaesthetic and a muscle relaxant; succinylcholine being the most widely used despite its long list of side effects[1]. Propofol has been shown to be a safe induction agent in children[2], propofol also depresses the pharyngeal & laryngeal reflexes more effectively than thiopentone[3]. So, the goal of our study was to see whether propofol could be used without a muscle relaxant to facilitate tracheal intubation in children.

Patients & Methods : After ethical committee approval, 82 children admitted for outpatient Dental & ENT surgeries were randomly allocated to one of two groups. Anaesthesia was induced by N2O:O2 and halothane (0.5 - 1.5%) . Group I received thiopentone (3mg.Kg^{-1}) followed by suxamethonim (1mg.kg-1). Group II received propofol (2mg.kg-1). Intubation was carried out after 45 seconds of assisted ventilation by the same blinded experienced anaesthesiologist. He recorded the conditions for laryngoscopy (as easy or difficult) & for intubation (as : 2 = easy without coughing, 1= easy with mild coughing, 0 = followed by severe coughing or impossible). The data were presented as mean ± standard error & analysed using the student's t test or Chi square analysis as appropriate.

Results & Discussion : The two groups were well matched (age = 5.9 ± 0.4 & 5.7 ± 0.4, weight = 21.9 ± 1.4 & 22 ± 1 1kg, M/F = 27/13 & 29/13). There was no statistical difference between the two groups as regards the conditions for laryngoscopy or intubation.

Conditions for	Laryngoscopy		Intubation		
	Easy	Difficult	0	1	2
Group I	39	1	1	7	32
Group II	42	0	3	9	30
	$X^2 = 1.06$	$p = 0.3$	$X^2 = 1.07$		$p = 0.53$

So, we have found that tracheal intubation was clinically acceptable in children in about 95% of the cases using either propofol alone or thiopentone & suxamethonium.

Conclusion : We conclude that propofol following a light inhalational induction is effective for tracheal intubation in children without the use of muscle relaxants.

A.162

VENTILATION WITH HALOTHANE IS LESS AFFECTED IN CHILDREN WITH LARYNGEAL MASK AIRWAY THAN WITH ENDOTRACHEAL TUBE

Jean REIGNIER, Mondher BEN AMEUR, Claude ECOFFEY

Département d'Anesthésie-Réanimation, Hôpital de Bicêtre, Université Paris - Sud, 94275 - Le Kremlin Bicêtre, FRANCE

Background and goal of the study: Because of respiratory depression, with a great inspiratory rib cage paradox, spontaneous ventilation with halothane anaesthesia should be avoided in children with endotracheal tube (1, 2). Endotracheal tubes have a much higher airflow resistance than laryngeal masks airway (3). Therefore, we sought to determine whether the lesser additional respiratory work induced by laryngeal mask airway authorizes or not spontaneous ventilation with halothane anaesthesia in children.

Materials and methods: We studied two groups of 6 to 24 months-old children free of cardiorespiratory and neurological disorders. They all were undergoing elective minor surgery: group 1 (n = 9) with laryngeal mask airway, group 2 (n = 10) with endotracheal tube. They received randomized administration of two halothane concentration: 1 and 1.5 Minimum Alveolar Concentration (MAC). We measured tidal volume (Vt), respiratory rate (RR), minute ventilation (VE, pneumotachygraph), CO2 end-tidal pressure (PetCO2) and we assessed inspiratory rib cage paradox by indices of amplitude (AI) and phase delay (DI). All the results are expressed as mean ± SD. Statistical analysis was made by a two ways ANOVA followed by Newman - Keuls test (p < 0.05 was considered significant).

Results and discussion: Age and weight were similar in both groups. All the respiratory parameters are summarized in the table :

	Vt/kg (ml/kg)		RR (/min)		VE/kg (ml/min/kg)	
	1	1.5	1	1.5	1	1.5
group1	9.4	7.1	41	43	385	301
	± 4.7	± 2.3*	± 6	± 7	± 179	±107*
group2	5.5	4.6	47	52	251	223
	± 1°	±1.2*°	± 11	± 13	± 36	± 29*

	PetCO2 (mmHg)		AI (%)		DI (%)	
	1	1.5	1	1.5	1	1.5
group1	41	46	23	32	18	15
	± 9	± 9	± 38	± 51	± 11	± 11
group2	40	44	59	106	40	49
	± 6	± 6	± 57	±86*°	±19*°	± 20*°

* p<0,05 vs MAC 1 , °p<0,05 vs group 1.

In accordance with literature, we found that minute-ventilation was depressed with halothane in a dose-dependant way (1). Tidal volume was less depressed with laryngeal mask airway than with endotracheal tube. The rib cage paradox indices were significantly (p < 0.001 for DI at 1.5 MAC) less altered with laryngeal mask airway than with endotracheal tube.

Conclusion: Spontaneous ventilation could be used with a laryngeal mask airway in 6 to 24 months-old children with halothane anaesthesia.

A.163

NEUROMUSCULAR BLOCKADE FOLLOWING MIVACURIUM IN CHILDREN DURING N20-HALOTHANE

Gilles Orliaguet, Benoit Plaud, Sylvie Calmatte*, Claude Ecoffey

Département d'Anesthésie - Réanimation, Université Paris-Sud, Hôpital de Bicêtre, 94275 - Le Kremlin-Bicêtre, FRANCE and * Welcome Laboratories

Background and goal of the study : Mivacurium is the latest, non depolarising neuromuscular blocking to become available in man. Pediatric data so far is limited (1). The aim of this study was to determine onset, duration of action and recovery characteristics in the child during N2O-halothane anesthesia.

Material and methods : Ten ASA status I-II children, aged between 1.3 and 6.8 years were studied following institutional approval and written informed consent from parents. All patients were scheduled for surgery requiring the use of neuromuscular blocking agents. Anaesthesia was induced with N2O (50 %) in O2 and halothane. The trachea was intubated and anaesthesia was maintained with an end-tidal halothane concentration of 1 MAC (age adjusted). Ventilation was controlled to maintain an end-tidal CO2 between 30 and 36 mmHg. Monitoring included ECG, non invasive blood pressure, end-tidal CO2, end-tidal halothane and Sp02. The ulnar nerve was stimulated supramaximally via skin electrodes at the wrist using a TOF stimulation every 10 sec. The force of contraction of the adductor pollicis was measured using a paediatric force transducer. After a stable recording had been achieved for 5 minutes, 0.2 mg.kg-1 of mivacurium was injected iv over 15 sec and flushed immediately. Following maximal blockade the stimulation rate was reduced to once every 20 sec. Onset time (time from injection to maximal blockade), clinical duration (time from injection to 25 % recovery), recovery index (time from 25 % recovery to 75 % recovery), total duration (time from injection to 90 % recovery) and the time from injection until T4 recovered to 80 % of T1 were measured. All results are expressed as mean ± SD. Systolic blood pressure and heart rate prior to injection and five minutes after were compared using ANOVA following by appropriate post-hoc test (p < 0.05 was considered statistically significant).

Results and discussion : Results are displayed on the table. All patients showed 100% block with the dose used. Systolic blood pressure was 93 ± 4 mmHg and 87 ± 3 mmHg respectively before and 5 min following injection of mivacurium, similarly heart rate was 99 ± 5 and 101 ± 5 bpm.

Table	mean ± SD	Range
Onset (sec)	68.5 ± 6.6	50 -120
Clinical duration (min)	12.5 ± 1.4	4 - 21.5
Recovery index (min)	3.4 ± 1.6	1.2 - 6
Total duration (min)	19.2 ± 5.9	11.3 - 31.9
Time to T4/T1 = 0.8 (min)	19.1 ± 6.4	10 - 28.7

Previous work has demonstrated the ED 95 of this drug to be 95µg/kg^{-1} in 2-12 years old children (2). As it is usually considered that the intubating dose is twice the ED 95, we therefore used 0.2 mg.kg^{-1}. Following this dose, the onset time (68 sec) is more rapid than estimated equipotent doses of atracurium in children during N2O-halothane anesthesia (3). The duration and recovery index are shorter.

Conclusion : At the dose of 0.2 mg.kg^{-1} in children mivacurium is a neuromuscular blocker which produces 100% blockade with a short onset time and a short duration of action.

A.164

RELATIONSHIP BETWEEN ARTERIAL PCO2 (PaCO2) AND END TIDAL CO2 (ETCO2) RECORDED THROUGH A LARYNGEAL MASK (LMA) IN CHILDREN BREATHING SPONTANEOUSLY.

LJ VAN OBBERGH, B ZEIPPEN, G MULLER, F VEYCKEMANS.
DPT of ANAESTHESIA ,UCL MEDICAL SCHOOL , 10 av Hippocrate ,1200 BRUSSELS

This study compare the ETCO2 and the PaCO2 in 25 ASA 1or 2 children undergoing Xray examination under propofol infusion and breathing spontaneously through a LMA (Size 1: 6 cases , Size 2: 19 cases) as we already described it (1).

ETCO2 was recorded through a 20 G catheter inserted 4 cm in the LMA with a DATEX NORMOCAP infrared capnometer calibrated before each case . 50% N2O in O2 was provided through a modified Ayre T piece , the fresh gas flow was adjusted to avoid any rebreathing on the capnogram . ETCO2 was recorded when a well identified plateau was reached during at least 5 min. . Arterial blood was drawn after a single puncture of the femoral artery and PaCO2 measured with a CIBA CORNING blood gas analyser.

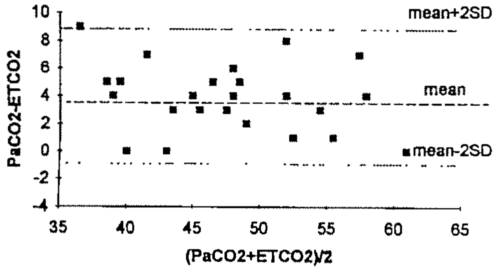
Linear regression (LR) was used to assess the correlation between the two parameters and the method described by Bland and Altman to measure their agreement (2) (Cf. fig 1)

RESULTS: (All results are expressed as MEAN ± SEM).

Age (Months):	37 ± 3.9
Weight (Kg):	19 ± 1.8
Respiratory rate (Breaths/min.)	22 ± 1.3
ETCO2 (mmHg):	45.2 ±1.2
PaCO2 (mmHg):	49.2 ± 1 3
Pa CO2-ETCO2 (mmHg):	3.8 ±0.5 SD ±3.4

LR of ETCO2 on PaCO2: PaCO2 = 10 +0.89 ETCO2 R=0.91 P=0.001

Fig 1: Agreement measure



CONCLUSIONS

Although the mean difference between the PaCO2 and the ETCO2 is near the values recorded with an endotracheal tube (3), the agreement limits seem to be greater and caution must be exercised when one is reading the ETCO2 with a LMA. The difference may be as great as 9 mmHg even in stable conditions .

A.165

EVALUATION OF THE EFFICACY OF FORCED-AIR WARMER (BAIR HUGGER) DURING SPINAL SURGERY IN CHILDREN

Isabelle Murat, Josée Bernière, Isabelle Constant

Dpt of Anaesthesia, Hopital Trousseau, Paris, France.

INTRODUCTION

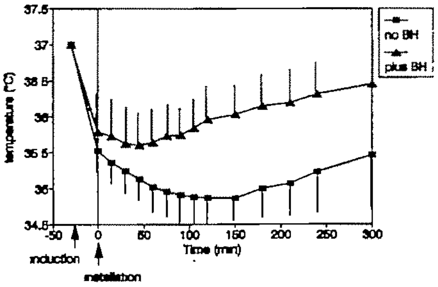
This study was undertaken to evaluate the efficacy of a forced-air warmer (Bair-Hugger) in children scheduled for surgical spinal fusion. Spinal surgery is an hemorrhagic procedure of long duration commonly associated with intraoperative hypothermia as active skin warming is difficult owing to the surgical position

METHODS

Fifty one consecutive children scheduled for posterior spinal fusion were studied. Anaesthesia was induced with propofol and pancuronium, and maintained with isoflurane and intermittent injections of pancuronium and phenoperidine. Moderate hypotension (mean arterial pressure 50-60 mmHg) was achieved with isoflurane and nitroglycerin (1-3 mcg.kg-1.min-1). Monitoring included EKG, arterial pressure, SpO2, expired gas (CO2, isoflurane) and rectal temperature. An open circuit with an heat moisture exchanger was used in all children. The study started after installation of the patient in the prone position. The study group (BH+; n=26) had the forced air warmer placed on the lower limbs, thus covering 30 to 40 % of the surface body area. In the control group (BH-; n=25), temperature was maintained with radiant heater placed near the head of the patient. Temperature of the operating room was 22-24°C. A wake-up test was performed after placement of the rods (CD material) upon request by the surgeon by discontinuing isoflurane and N2O. Temperature was continuously monitored during surgery and during the first two hours in the recovery room. Demographic data, temperature values, blood loss, time to wake-up test and extubation were compared between the two groups with the use of student's T test. P values of 0.05 or less were considered as significant. Results are mean ± SD.

RESULTS

No differences between groups were observed regarding age (BH- vs. BH+; 14.9 ±2.2 vs. 14.7 ± 1.7 years), weight 45.6 ± 8 9 vs. 47.9 ± 13.8 kg), duration of surgery (5.8 ± 2.0 vs. 4.8 ± 1.2 h), duration of induction before installation (33.4 ± 12.5 vs. 32.5 ± 16.2 min). No differences were also observed for time to obtain a positive wake-up test, time to extubation and total blood loss per vertebra. The evolution of mean rectal temperature in the two groups is indicated on the figure.



CONCLUSION

The Bair-Hugger was more effective than conventional methods to maintain body temperature during surgery despite only 30 to 40 % of body surface area was covered during surgery.

A.166

EVALUATION OF A FORCED-AIR WARMER (BAIR-HUGGER) IN MAINTAINING BODY TEMPERATURE IN INFANTS DURING CLEFT PALATE SURGERY.

I. Murat, M. Delorme, V. Piat, M.C. Dubois

Dpt of Anaesthesia, Hopital Armand Trousseau, Paris, France.

INTRODUCTION

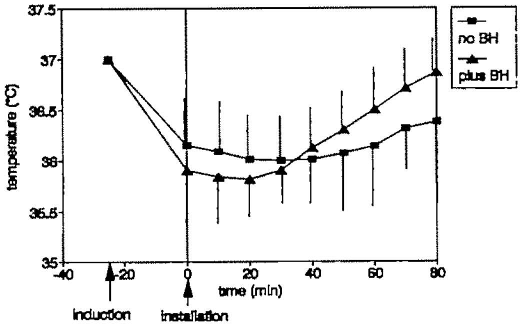
Congenital clefts of the lip and/or palate are usually repaired early in infancy for cosmetic reasons and to improve the development of the alveolar dental arch. This study was undertaken to assess the efficacy of a forced-air warmer (Bair-Hugger) in maintaining body temperature during surgery as compared to conventional means.

METHODS

Infants weighting less than 10 kg scheduled for cleft of the lip or palate repair were assigned to two groups. In the study group (BH+; n=25), the Bair-Hugger was placed on the lower part of the body after induction of anaesthesia and tracheal intubation. In the control group (BH-; n=19), body temperature was maintained with a water mattress placed under the body covered with surgical drapes. Temperature was monitored rectally every 10 min during surgery and for the first 2 hours in the recovery room. In both groups, anaesthesia was induced with halothane by face mask and maintained with isoflurane and fentanyl (2-3 mcg.kg-1). An open circuit with an heat moisture exchanger was used in all infants. Temperature of the operating room was set at 24°C in both groups. Comparisons of demographic data, temperature values, time to extubation, were done using student's t-test. $P<0.05$ was considered as significant. Results are mean ± SD.

RESULTS

The two groups were identical regarding age (BH- vs. BH+; 5.3 ± 2.6 vs. 5.1 ± 2.2 months), weight (6.5 ± 1.3 vs. 6.3 ± 1.4 kg) and duration of surgery (95 ± 26 vs. 97 ± 23 min). No differences in rectal temperatures were observed between groups during surgery (figure). Time to extubation was also identical in the 2 groups (23 ± 10.5 vs. 26.4 ± 18.7 min). No differences were observed in the recovery room while more infants in the BH- group required a radiant warmer to maintain their temperature than in the BH+ group.



CONCLUSION

Both forced-air warmer and water mattress were effective in maintaining central temperature in infants when operating room temperature is as high as 24°C.

A.167

COMPARISON OF DOBUTAMINE WITH ENOXIMONE FOLLOWING OPEN HEART SURGERY IN SMALL CHILDREN

P. Innes, E. Allsop, J.Lockie, C. Kirton, P.Booker. Department of Paediatric Anaesthesia, Royal Liverpool Children's Hospital, Liverpool, England.

Background and goal of study: Dobutamine and enoximone are often used following heart surgery, though few studies have examined their respective haemodynamic effects in children. This study aims to compare the effects of these 2 drugs in children having open heart surgery.

Materials and methods: 25 children, mean age 1.22 yrs (0.42-3.83yrs), scheduled for elective correction of either tetralogy of Fallot or atrioventricular septal defect (AVSD) were randomly allocated into one of two groups. Group 1 received dobutamine (D) (10mcg/kg/min) and phenoxybenzamine 1 mg/kg and group 2 enoximone (E) 10 mcg/kg/min following a loading dose of 0.5mg/kg. The trial drug was started 10 minutes prior to the anticipated cessation of cardiopulmonary bypass (CPB). Heart rate (HR), mean systemic and pulmonary arterial pressures (MAP & MPAP), central venous and left atrial pressures (CVP & LAP) and cardiac index (CI) by the thermodilution technique were measured at 0.25, 0.5, 0.75, 1, 1.5, 2, 3, 4, 5 and 6 hours after CPB. Systemic vascular resistence index (SVRI) and left ventricular stroke work index (LVSWI) were calculated using conventional formulae. Variables for each patient were plotted against time and area under the curve calculated giving a mean value for each variable. Statistical analysis was by the unpaired students t test.

Results and discussion: There were no significant differences between the 2 groups of patients with respect to age, operation type and aortic cross-clamp times:- D: 77.2 mins (65-85) E: 76.7 mins (65-89). 3 patients (E:2, D:1) also required adrenaline in order to be weaned from CPB. There was no significant difference between the 2 groups with respect to HR, CVP, LAP and MPAP and SVRI. D was associated with a higher MAP (D 61.7mmHg 7.9sd;E 55.8mmHg 5.6sd:$P=0.05$); a higher CI (D 2.89 L/min/m2 0.65sd;E 2.40 L/min/m2 0.38sd:$P<0.05$); and a higher LVSWI (D 12.98 J/m2 4.97sd;E 9.53 J/m2 1.97sd:$P<0.05$) indicating greater inotropic effect.

Conclusion: This study shows that enoximone can be used successfully to wean children from CPB. However, dobutamine, in combination with phenoxybenzamine, has greater inotropic and similar vasodilatory properties than enoximone in the doses used.

A.168

EXREACORPOREAL MEMBRANE OXYGENATION FOR POSTOPERATIVE CARDIAC SUPPORT IN NEWBORN INFANTS: FIRST CLINICAL DATA

A Marcassa, C Sorbara, G Stellin, D Pittarello, GP Giron

Department of Anaesthesia and Intensive Care, University of Padua, Padua, Italy

Background and goal of study: Extracorporeal membrane oxygenation (ECMO) has been used successfully to treat newborn infants with respiratory failure that is unresponsive to ventilatory and pharmacologic support. We describe our experience of the use of veno-arterial ECMO to support cardiac function in paediatric patients who have developed low cardiac output syndrome after surgical repair of congenital heart defects.

Materials and methods: From March till October 1992 we have treated 6 newborn infants (age 2-32 days, weight 2.7-3.8 kg) who required ECMO in the operating room since they could not be weaned from cardiopulmonary bypass after open cardiac operations (3 hypoplastic left heart syndromes, 1 transposition of the great arteries, 2 complex obstructive lesions of the right ventricle). We performed thoracic cannulations using a 10F cannula for the aorta and a 16F cannula for the right atrium. Pump flow was >110 ml/kg/min in all patients. The ECMO circuit consisted of a Biomedicus centrifugal pump, a SciMed membrane lung and a SciMed heat exchanger.

Results and discussion: The duration of ECMO ranged from 4 to 143 h (mean 55.6 h). 4/6 patients could be weaned from ECMO. Only 1/4 is a long-term survivor. The other three children died in the intensive care unit; two shortly after weaning from ECMO and the third after four days. Two patients could not be weaned from ECMO because of irreversible cardiac failure. Bleeding was the most frequent complication averaging 6.45 ml/kg/h. One patient had an intracranial haemorrhage. Renal insufficiency developed in two patients. No technical complications of ECMO occured.

Conclusion: ECMO is a successful procedure in treatment of neonatal respiratory failure with an overall survival rate in the order of 85%. Veno-arterial ECMO can also be used for temporary circulatory support in severe cardiac failure after cardiac surgery. Similar to previous reports which show that survival rate is correlated with the time of ECMO initiation, our results indicate that patients requiring ECMO in the operating room have a high mortality.

A.169

DIAMORPHINE/BUPIVACAINE MIXTURE VS PLAIN BUPIVACAINE: A COMPARISON OF EPIDURAL INFUSIONS IN LABOUR

CR Bailey, R Ruggier, IL Findley

Department of Anaesthetics, St Georges Hospital, London, UK

Background and goal of study: Analgesia in labour should be safe, effective and feasible. Both local anaesthetics and opioids are effective via the epidural route and the aim of this study was to compare plain bupivacaine 0.125% run at 10 ml/h with a low dose bupivacaine/diamorphine infusion run at the same rate. By using the lowest effective dose of each drug in combination we attempted to eliminate any side effects whilst providing excellent analgesia in labour.

Patients and methods: 50 healthy patients in active labour were studied following Ethics committee approval. After insertion of the epidural a loading dose of 8 ml 0.5% plain bupivacaine was given to all patients, who were then randomised to receive either plain bupivacaine 0.125% or plain bupivacaine 0.0625%/diamorphine 0.005%. Hourly Visual Analgue Pain Scores (VAPS) were obtained by Midwives and top-ups of 10 ml 0.25% bupivacaine were given if required. Assessment of motor blockade and sensory level were repeated every hour. Blood pressure, heart rate, respiratory rate and fetal heart rate were recorded every 30 min. Mode of delivery and condition of neonate were noted and a questionnaire completed by the mother on the day after delivery which included direct questioning for symptoms such as pruritus and nausea.

Results and discussion: Age, weight and height were similar in both groups. Patients in the diamorphine group had significantly more painfree hours (54 vs 32 in control group, $p<0.01$ by Chi-square) and greater satisfaction with the infusion, but there was no difference in the incidence of hypotension or instrumental delivery, number of top-ups, duration of second stage or extent of motor block. Moreover, patients in the diamorphine group had a higher incidence of pruritus (44% vs 0% in control group). Enever et al used a diamorphine/bupivacaine mixture in labour but patients received only 1.05 mg of diamorphine/h compared to 3.08 mg/h in this study and had a higher incidence of motor block but low incidence of pruritus, and results from other studies show that both diamorphine and bupivacaine produce dose-related side effects.

Conclusion: The addition of epidural diamorphine at 0.5 mg/h to a solution of 0.0625% bupivacaine produces additional opioid-related complications without reducing the side effects which occur with 0.125% bupivacaine alone.

A.170

PATIENT CONTROLLED EPIDURAL ANALGESIA VS. INTERMITTENT INJECTIONS DURING LABOR USING 0.125% BUPIVACAINE AND SUFENTANIL.

J. Baudot, J.D. Vertommen, H. Van Aken.

Department of Anesthesiology, University Hospitals,
Katholieke Universiteit Leuven,
Herestraat 49 B-3000 Leuven, Belgium.

Background and goal of study: The addition of 7.5 μg sufentanil to 0.125% bupivacaine with epinephrine (1:800,000) enhances the quality of analgesia during labor without depressing the neonate when the mixture is given as intermittent 10 ml injections. (1,2). The present study was undertaken to investigate if patient controlled epidural analgesia (PCEA) using an identical anesthetic mixture provides a comparable quality of analgesia.

Materials and methods: With institutional approval and informed consent, 74 pregnant women who requested epidural analgesia for labor were included in this prospective study and randomly assigned to 2 groups of 37 women each. They received either intermittent injections given by an anesthesiologist (A), or PCEA (B). In all women analgesia was induced by epidural injection of 10 ml containing 12.5 mg bupivacaine, 12.5 μg epinephrine and 7.5 μg sufentanil. In group A analgesia was further maintained by 10 ml injections of the same mixture on request. In group B, analgesia was provided by self administration of 4ml boli of 0.125% bupivacaine with epinephrine (1:800,000) plus sufentanil 0.75μg/ml with a lock-out interval of 20 min. The quality of analgesia was assessed on a linear visual analog scale before the first epidural injection, then each hour, and during episiotomy, delivery, and suturing. Patient satisfaction was also rated on a visual analog scale, 1 hour after delivery. The duration of analgesia, the degree of motor blockade, and the total volume of anesthetic mixture were noted. The neonates were evaluated by Apgar scores. Statistical analyses were done by Student-t test and chi-squares. A P value < 0.05 indicated significance.

Results and discussion: Patient characteristics of both groups were comparable. The mean pain relief in both groups was 80% and there was no difference in pain score between the groups during episiotomy, delivery, or suturing. Motor blockade and type of delivery did not differ between the groups. Patients in group B used less anesthetic mixture, but this difference did not reach statistical significance. Although in group A the delay between request and injection was significantly longer than in group B, patient satisfaction was similar.

Conclusion: PCEA and intermittent injections using 0.125% bupivacaine and sufentanil provide a comparable quality of analgesia during labor.

A.171

ADEQUATE PAIN RELIEF WITH EPIDURAL ANALGESIA DURING LABOR : WHY ARE WOMEN STILL DISSATISFIED ?

Jamil Hamza, Patrick Narchi, M Elhaddoury, Dan Benhamou

Département d'Anesthésie, Université Paris Sud, Hôpital
Antoine Béclère, 92141 Clamart, France.

Background and goal of study: Inadequate pain relief with lumbar epidural analgesia (LEA) is a classical cause of parturient's dissatisfaction. However, even when this technique has been efficient, some women remain dissatisfied. The goal of this study was to define other factors associated with patient's dissatisfaction in a large obstetrical population.

Materials and methods: After institutional approval and over a 2 years period, all parturients who delivered vaginally under LEA participated to this study. All data related to LEA and the delivery period were noted. During the 3 first days postdelivery, a questionnaire aimed at understanding the reasons of dissatisfaction about LEA was given to these patients. Specific items were the following: global satisfaction, adequacy of pain relief, quotation of pain associated with epidural puncture, relationship with the anesthetist, time interval between request and epidural puncture. The first step of the study was to assess the role of the inadequacy of pain relief as a factor of dissatisfaction. The second step aimed at assessing in the subgroup of women who were adequately relieved of pain, the factors associated with their dissatisfaction. Statistics of all collected data included either unpaired Student's t-test or a Chi square test for qualitative data: $p<0.05$ was considered as statistically significant.

Results and discussion: Of the 1297 women who were included, 1058 (82%) had adequate pain relief whereas 239 (18%) had not. Global satisfaction in patients who had inadequate pain relief was significantly lower than in those with adequate pain relief. Women **adequately relieved** were thus divided into 2 groups with respect to their overall satisfaction concerning LEA: Satisfied (S) n=1034 and dissatisfied (**disS**) n=24. Demographic data, duration of labor, newborn's weight, parity, cervical dilatation at the time of puncture and the total dose of bupivacaine were comparable between both groups. Risk factors associated with patient's dissatisfaction with LEA were the following: a bad human relationship with the anesthetist performing EA, a painful epidural technique and a long delay between request and puncture (Figure).

This study confirms that inadequate pain relief remains a major cause (84.4 %) of dissatisfaction with LEA. However, a long time interval between request and puncture, a painful epidural puncture and a bad relationship between the patient and the anesthetist are to be considered as significant factors of dissatisfaction even if pain relief is adequate throughout labor.

Conclusion: Anesthetists must be aware of the importance of these factors and that pain relief is not the only goal to achieve in order to satisfy laboring women.

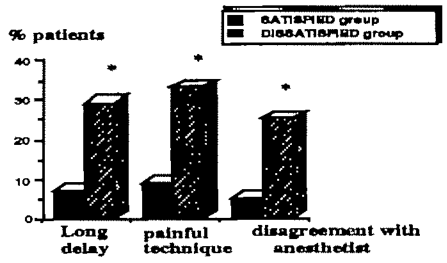

Figure 1: % patients presenting these features in the group adequately relieved (n=1058)

A.172

SPINAL ANESTHESIA FOR C SECTION : ADDITION OF PHENYLEPHRINE TO EPHEDRINE FOR PREVENTION OF MATERNAL HYPOTENSION.

Anne-Valérie Thirion, Michel Henry, Annette Cornet,
Jeanne Seebacher, Pierre Viars.
Department of Anaesthesiology, CHU Pitié-Salpêtrière, Paris, France.

Ephedrine is considered as the vasopressor of choice in obstetrical anesthesia. However, particularly for C section performed under spinal anesthesia, larges doses are needed which may lead to side effects (i.e. tachyphylaxia, tachycardia). Recently, clinical studies shown phenylephrine, an alpha agonist, to be as efficacious and safe as ephedrine (1). This study was designed to evaluate whether the addition of a small dose of phenylephrine to an ephedrine infusion could provide hemodynamic stability throughout C section performed under spinal anesthesia.

Patients and methods: Thirty patients ASA I scheduled for elective C section were studied. After 25 ml/kg of ringer lactate solution preloading over 30 minutes, spinal anesthesia was induced with 12,5 mg Bupivacaïne 0,5 % and 0,1 mg Morphine in the left lateral decubitus position. At the time of the spinal puncture, patients received a continuous I.V. infusion of phenylephrine (60 mcg) and ephedrine (7,5 mg) over a 15 minutes period. Additional ephedrine was given in 3 mg boluses if blood pressure was not stable. These patients were compared to 30 patients ASA I who underwent the same anesthetic and surgical procedure but received a continuous infusion of only ephedrine 7,5 mg over a 15 minutes period.

Results: Maternal weight, height, neonatal Apgar scores are not statistically different between the two groups. Maternal blood pressure was stable throughout the surgical procedure in both groups but more patients receiving only ephedrine required additional ephedrine (table). A significant increase in maternal heart rate (HR) was noted only in patients receiving ephedrine (ANOVA $p<0,05$). Besides post-infusion HR was higher in this group of patients.

	Additional Ephedrine		
nb of boluses	0-1	2 - 4	> 4
Ephedrine + Neo	n = 18	n = 9	n = 3
Ephedrine	n = 7	n = 12	n = 11

Conclusions: We conclude that the addition of a small dose of phenylephrine to an ephedrine infusion was easily useable and effective in preventing maternal hypotension without increasing maternal heart rate.

A.173

HEADACHE - NEW NEEDLES AND SPINAL ANESTHESIA FOR C. SECTION

F. Thormann, M. Henry, J.P. Soler,
J. Seebacher, P. Viars
Department of Anesthesiology.
CHU Pitié-Salpêtrière. Paris. France

Background and goal of study. The highest incidence of postdural puncture headache (PDPH) occurs in obstetric patients (1). With the blunt ogival spinal needle, with side opening, we performed 300 c. section (ASA I) without any severe PDPH, like other authors (2). The aim of this study was to collect the different headache after spinal c.-section with different blunt and ogival needles.

Materials and method. 103 ASA I parturients underwent elective c.-section with the same anesthetic protocol : left uterine displacement, filling 25 ml/kg of saline and ephedrine (continuous infusion and bolus), 2) intrathecal injection of 0.1 mg of morphine and 12.5 mg of hyperbaric bupivacaine. The anesthetist was free to choice between a 1) 22 gauche Sprotte needle, 2) 24 gauche Sprotte needle, 3) 25 gauge modified Whitacre (Vygon-Portex). On postoperative days (1 to 6) a blinded anesthetic nurse evaluated each patient to determine the incidence of headache ; then the anesthetist, after patient examination, classified the headache according to three groups 1) **minor**, transitory headache (postural or not) not requiring any analgesic; 2) PDPH = postural headache always treated by recumbent position : a) **middle**, requiring simple oral analgesics, lasting 2 or 3 days, b) **severe**, incapaciting for the mother, lasting a week or more ; the only efficacious treatment is the blood-patch.

Results. We don't find any severe PDPH ; there is a tendency, to be confirmed, to a highest incidence of middle PDPH with the 22 gauge needle ; the headache are not correlated to difficult punction.

n	Needle	Gauge	Minor	Middle (a)	Severe(b)
48	Sprotte	22	5	4	0
35	Sprotte	24	5	1	0
20	Whitacre	25	2	1	0

Discussion. The lack of severe PDPH is confirmed in ASA I. PDPH decreased with blunt ogival needle ; but higher gauge is yet associated with a higher incidence of middle PDPH (well accepted by the mother).

Conclusion. We can propose spinal anesthesia with the blunt ogival needle at gravid young women who are the classical highest risk of severe PDPH.

A.174

BEST QUINCKE POINT NEEDLE FOR CAESAREAN SECTION

Gordon Lyons

St James' University Hospital,
Leeds, UK.

The incidence of post dural puncture headache is influenced by age, sex and the mode of spinal anaesthesia. Of particular importance is the size and nature of the spinal needle. A number of studies claim a reduction in the incidence of headache following spinal anaesthesia for Caesarean section if a pencil point needle is used in preference to a Quincke point. Before the case for pencil point needles can be accepted, it is necessary to establish which Quincke point needle is the best for Caesarean section. This study aimed to establish the best Quincke point spinal needle for Caesarean section.

Hospital ethics committee approved this study. 300 women scheduled for elective Caesarean section under combined spinal/epidural anaesthesia were randomised to receive their anaesthetic with a 26 gauge, a 27 gauge, and a 29 gauge needle. Established clinical procedures were followed. Observations included:
Time from gloves to intrathecal injection
Number of suspected dural punctures
CSF seen/not seen
Anaesthetist's assessment of block
Patient's assessment of block
Incidence of postoperative headache

The 29 gauge needle was associated with more failed sitings and need for epidural support than the other two needles. This was statistically significant. Five patients in the 26 gauge group required epidural blood patches, compared with one each in the other groups. This did not reach statistical significance. In conclusion, the 29 gauge needle had the most failures, and the 26 gauge needle, the most headaches. the 27 gauge needle appears to be the best Quincke point needle for Caesarean section.

A.175

NEONATAL GLYCEMIA: DOES THE MATERNAL IV FLUID REGIMEN DURING LABOR MAKE A DIFFERENCE?

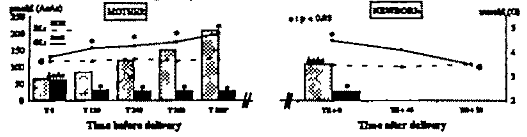
C. Menigaux, J. Hamza, P. Bougnières, Cl. Saint-maurice

Departement of Anesthesia, Inserm U342, Hospital Saint
Vincent de Paul, Paris, France

Background and goal of the study: Maternal glucose infusion during labor was recommanded to avoid maternal and fetal hypoglycemia(hypoG). However, when uncontrolled this practice may lead to neonatal hypoG(1). Therefore, we decided to prospectively compare the maternal and neonatal consequences of two maternal iv fluid regimen with or with out controlled glucose administration during vaginal delivery.

Patients and methods: 20 ASA 1 parturients with a normal singleton pregnancy entered the study in active labor (cervical dilatation < 3 cm). After a fasting duration of at least 10 hours, they were randomly allocated to receive as a continuous iv infusion either 20 ml/h of 50% dextrose (150 mg/kg/h of glucose) (group GL) or 20 ml/h of Ringer lactate (group RL). In both group, a basal iv infusion of 100 ml/h of Ringer lactate was administered with a iv bolus before epidural analgesia(EA).of 15 ml/kg. Glycemia(G), aceto-acetic acid(AcAc), lactic acid(L), free fatty acid(FFA) were measured every two hours until delivery in maternal plasma. In the newborn G, AcAc, L, FFA and insulinemia(Ins) were measured at birth, and also G at 45 and 90 min of life using dextrostix. Statistical analysis used paired and unpaired Student's t test.

Results and discussion: Weight, age, duration of labor and initial biological parameters were similar. Despite a fasting period > 10 h, no parturient had a G < 3,3 mmol/l throughout labor even in the RL group. In contrast one parturient in the GL group had a G > 6,6 mmol/l which is a risk factor for neonatal hypoG(1). However neonatal G was never < 2,75 mmol/l neither at birth nor at 45 and 90 min of life. This was not surprising as neonatal Ins was always < 5 IU/ml well below the level at risk for neonatal hypoG(1). In addition neonatal AcAc at birth was by far higher in RL group (108 ± 45 vs 28 ± 12 µmol/l), which is explained by higher maternal AcAc in RL group as AcAc cross the placenta. AcAc can replace glucose for fetal and neonatal brain's metabolism allowing a better tolerance to hypoG(2). We believe that the stable and normal neonatal G of RL group was due to their higher level of AcAc.



Conclusion: Our study shows that glucose administered at a moderate rate of continuous infusion does not induce neonatal hyperIns or hypoG. However the lack of glucose in normal parturients in active labor under EA does not appear to be detrimental for maternal or neonatal G.

A.176

EPIDURAL CLONIDINE ANALGESIA AFTER MAJOR GYNAECOLOGICAL SURGERY

Ivan Smilov, Borislav Borissov

**University Hospital of Obstetrics and Gynaecology,
Sofia, Bulgaria**

Background and goal of study: After it has been established that clonidine may inhibit the release of substance P from the afferents in the spinal horn by mean of α_2-stimulation, the potential benefits of epidural clonidine on postoperative pain has been extensively studied. The present study was undertaken to elucidate whether epidural clonidine is effective in providing analgesia after gynaecological surgery.

Materials and methods: Twenty ASA class II patients undergoing radical hysterectomy were studied. An epidural catheter was placed preoperatively at the L1/L2 or L2/L3 level. After determination of correct placement by administration of a test dose, each patient received general anaesthesia. Sixty min after completion of surgery, 3 $mcg.kg^{-1}$ of clonidine were administered via the catheter. Postoperative pain was assessed by a visual analogue scale.

Results and discussion: The duration of pain relief acheived with epidural clonidine only lasted between two and five hours. Moderate hypotension which did not require iv volume or vasopressors accompanied the clonidine administration.

Conclusion: This study shows that epidural clonidine can provide satisfactory postoperative pain relief with an acceptable level of side effects.

A.177

MECHANISMS OF ECG CHANGES DURING CAESAREAN SECTION (CS) - A HYPOTHESIS.

Mikael Svanström, Göran Johansson, Eva Bålfors.

Department of Anaesthesia, University of Umeå, Umeå, Sweden.

Background & goal of study: Recent studies have shown that 25 to 64% of women undergoing CS develop short-lived ECG changes, the configuration of which suggest an ischaemic origin (1). One other study has failed to confirm these data (2). As yet, there is no proof that the ECG changes represent myocardial ischaemia, neither has their cause been clarified. The goal of this study was to provide additional information on the time course of new spatial ECG changes in relation to systemic blood pressure variations and oxytocin administration in CS.

Patients & methods: After institutional approval and informed consent, 12 healthy women scheduled for elective CS under combined spinal/epidural anaesthesia were studied. Invasive blood pressure was recorded in 8/12. Computerized vectorcardiography (VCG) was used to detect electrocardiographic changes. STC-VM, e.g. the change of the spatial ST-vector magnitude was the ST-variable which was followed continuously. A change of STC-VM by more than 50 uV has previously been described as abnormal. Patients were kept in the left lateral tilt until delivery after which oxytocin was administered iv at 10 IU. Nasal oxygen was given and oxygenation monitored by pulse oximetry. Iv ephedrine was given as required to maintain systolic blood pressure above 95 mm Hg before delivery.

Results & discussion: 10/12 (83%) developed abnormal STC-VM changes (range 60 to 280 uV), which in all patients occurred within 60 sec (range 20 to 60 sec) of the oxytocin injection and were of short-lived duration (range 90 to 210 sec). All ST-changes were characterized by depression and were horizontal or downsloping. Heart rate was not significantly altered. 6/8 who had invasive blood pressure measurement displayed STC-VM changes. Diastolic blood pressure decreased in 7/8 (range 36% to 57%). The change of STC-VM correlated with the fall in diastolic blood pressure. We conclude 1. that iv oxytocin produced diastolic arterial hypotension, consistent with the vasodilating property of this drug (3), 2. this hypotension frequently caused marked ST-segement depression. We suggest that myocardial underperfusion due to hypotension and possibly increased coronary vasomototor tone by oxytocin (4) is responsible for the ECG changes. Further studies are needed to precisely determine the role of oxytocin in this respect.

A.178

PROLONGED (> 1 WEEK) SEDATION WITH MIDAZOLAM IN ICU PATIENTS: EFFICACY, SAFETY AND PHARMACOKINETICS

L Heytens, L Bossaert

Department of Intensive Care, University Hospital, Antwerp, Belgium

Objective : to study the efficacy and safety of midazolam in very prolonged (at least 7 days) sedation of traumatized patients in a surgical Intensive Care Unit. Special attention was also given to the plasma concentrations during sedation and after the cessation of the midazolam infusion.

Methods : 12 patients 16 - 65 y with major chest trauma requiring prolonged ventilatory support were enrolled in the study (excluded were patients with head injury, hypotension, renal and liver failure). Sedation consisted of midazolam 5 mg/hr supplemented with fentanyl 2 µg/kg/hr. The dose was adjusted according to clinical need with a maximum midazolam dose of 0.2 mg/kg/hr.

The following variables were recorded : A 10 point Visual Analog Scale of agitation, pain and alertness every 4 hours; evaluation of the degree of sedation using a 4 point scale (1 = insufficient, 2 = moderate, 3 = good, 4 = unresponsive), speed of infusion of midazolam (mg/kg/hr) and plasma concentrations of midazolam (every 3 days during the study and at 4, 3, 2, 1 and 0 hours before termination of the midazolam infusion and 4, 8, 12, 16, 26, 48 and 72 hours after stopping the infusion).

Results : The mean duration of sedation was 18.9 ± 7.2 days. The quality of the sedation was considered 'unresponsive' in 40 %, good in 36%, moderate in 19% and insufficient in 5% of the evaluations. The mean midazolam dose had to be increased from a mean of 5.0 ± 0.0 mg/hr to 10.3 ± 3.6 mg/hr over the first week; an observation made in the majority of the patients. Steady-state plasma concentrations before termination of the infusion ranged from 0.31 - 2.47 µg/ml (mean 0.80 ± 0.79 µg/ml) dropping to 0.03 - 1.11 µg/ml (mean 0.22 ± 0.34 µg/ml) after 12 hours. Prolonged rest sedation (> 48 hrs) was observed in 1 patient and agitation, interpreted as withdrawal symptoms, in 8 patients.

Conclusions : These findings illustrate that a continuous infusion of midazolam/fentanyl can provide a good level of sedation for up to several weeks in the majority of these patients. The plasma concentrations of midazolam show large interindividual differences, even at the same level of sedation. A moderate degree of tolerance to either or both of the drugs used as well as withdrawal symptoms have to be anticipated.

A.179

INCIDENCE OF BACTERIAL MAXILLARY SINUSITIS IN CRITICALLY ILL PATIENTS WITH RADIOLOGIC MAXILLARY SINUSITIS.

L. Bodin, P. Laurent, T. Do-Khac, A. Zouaoui, G. Lamas, E. Cambau, J. J. Rouby, P. Viars.

Département d'Anesthésie-Réanimation. GH Pitié-Salpétrière Université Paris VI France

Introduction : Maxillary sinusitis frequently occurs in mechanically ventilated patients. The aim of this prospective study was to assess the incidence of bacterial maxillary sinusitis in intubated critically ill patients with radiologic maxillary sinusitis.

Methods: 127 mechanically ventilated patients (mean age : 56 ± 15 years) were prospectively enrolled in the study after informed consent and institutional approval was obtained. Within 48 hours following admission to the SICU, a paranasal CT scan demonstrated radiologic maxillary sinusitis defined as an air-fluid level opacity or a total opacification of the maxillary sinus. Within 24 hours following the CT scan, a transnasal puncture of maxillary sinuses was performed under general anesthesia, after desinfection of the nares. A nasal swab before and 20 minutes after a large desinfection of the nares using a polyvidone-iodine solution was performed for evaluating efficency of the nasal desinfection. Sinus contents were bacteriologically processed including cell count and quantitative analysis. A bacterial sinusitis was defined as the presence of altered polymorphonuclear leukocytes (> 5 per oil immersion field) associated or not with a positive culture. In case of inadequate desinfection of the nare (positive nasal swab after desinfection), high bacterial concentrations ($\geq 10^3$ cfu/ml and at least 10 fold greater than bacterial concentrations found in the nare) were required for the diagnosis of bacterial sinusitis.

Results : 194 maxillary sinuses were punctured in 127 patients (unilateral puncture n = 60, bilateral puncture n = 67). Desinfection of the nares was adequate in 91 cases (negative nasal swab after desinfection). According to cytologic and bacteriologic criteria, bacterial maxillary sinusitis was diagnosed in 51 patients. The incidence of bacterial maxillary sinusitis among patients with radiologic sinusitis was of 38%.

Conclusion: Radiologic maxillary sinusitis frequently occurs in intubated critically ill patients. However, these radiologic sinusitis are not always due to an infectious process since only 38% of our patients had cytologic and bacteriologic criteria demonstrating bacterial maxillary sinusitis.

A.180

REASSESSMENT OF BRONCHOALVEOLAR LAVAGE IN THE DIAGNOSIS OF POST TRAUMATIC PULMONARY FAT EMBOLISM

Olivier Mimoz, Alain Edouard, Laurent Beydon,
Françis Bonnet et Kamran Samii

Anesthésie Réanimation et Anatomo-Pathologie,
Hôpitaux de Bicêtre (F94275 Le Kremlin Bicêtre)
et Henri Mondor (F94010 Créteil)

Background and goal of the study: The importance of fat droplets within cells recovered by bronchoalveolar lavage (BAL) has been proposed as a rapid and specific method for establishing the diagnosis of post-traumatic pulmonary fat embolism (PFE) (1). However, the low value (5%) retained as the significant threshold may be questionable. Thus, the goal of the present prospective study was to compare the results of BAL with the clinical patterns of PFE in trauma patients.
Materials and methods: BALs were performed in 48 patients (age: 33±16 yrs, ISS: 39±13, SAPS: 11±3, mean ± SD) during the first 3 days after trauma to determine the percentage of lavage cells containing intracellular fat droplets. On the 5th post-traumatic day, patients were included into one of 3 groups according to the presence or not of the 3 major features of the fat embolism syndrome described by Gurd (2) (F1: petechial rash, F2: ARDS, F3: neurological disorders). PFE was considered as definite when 2 out of 3 major features were observed (the presence of F1 is mandatory in cases of associated thoracic or cranial trauma), likely when F2 or F3 were present, but could be explained by a specific injury (pulmonary contusion, cranial trauma) and unlikely in the other cases. At that time, the attending physician was unaware of the BALs' results. BAL was done and analyzed as previously described by Chastre et al (1). Fat droplets were stained with Soudan 3.
Results: the percentage of lavage cells containing intracellular fat droplets for the 3 groups of patients is shown in this table.

clinical PFE		% of cells containing fat droplets				
	n	0-5	6-29	30-49	50-69	70-100
Definite	4	0	0	0	0	4
Likely	4	1	0	1	1	1
Unlikely	40	20	14	4	2	0

Conclusion: This study documents that a high percentage (>70%) of lavage cells containing intracellular fat droplets is observed when PFE is clinically obvious. In questionable cases or when PFE is unlikely, BAL fails to contribute to the diagnosis.

HISTOLOGIC ASPECTS OF PULMONARY BAROTRAUMA IN CRITICALLY ILL PATIENTS WITH ACUTE RESPIRATORY FAILURE

Rouby J. J., Lherm T., Martin de Lassale E., Poete P.,
Bodin L., Viars P.

Département d'Anesthésie-Réanimation,GH Pitié-Salpêtrière,
Université Paris VI. France.

Introduction : Histologic studies on human lungs were performed to provide a comprehensive description of lung barotrauma in patients with ARDS requiring prolonged mechanical ventilation.

Methods: The lungs of 30 ARDS patients (mean age 34 ± 10 years) who died after a period of mechanical ventilation > 48 hrs, were histologically examined in the immediate postmortem period. Patients suspect of emphysema at the time of admission to the SICU and patients over the age of 50 were excluded. Characteristics of mechanical ventilation were prospectively recorded and compared with lung histology.

Results: One third of the patients presented one or several episodes of pneumothorax while on mechanical ventilation. At autopsy, pleural cysts of varying size (0.5 to 4 cms), airspace enlargement – defined as the presence of emphysema and/or intraparenchymal pseudocysts – and bronchiolar dilatation were found in 26 of the 30 lungs examined (86%). Mild airspace enlargement (1 to 2.5 mm internal diameter) were observed in 12 lungs and severe airspace enlargement (2.6 to 40 mm internal diameter) were found in 14 lungs. Patients with severe airspace enlargement had a significantly greater incidence of pneumothorax (8 vs 2, $p < 0.05$), were ventilated using higher peak airway pressures (56 ± 18 cm H_2O vs 44 ± 10 cm H_2O, $p < 0.05$) and tidal volumes (12 ± 3 ml/kg vs 9 ± 2 ml/kg, $p < 0.05$), were exposed significantly longer to toxic levels of oxygen (8.6 ± 9.4 days vs 1.9 ± 2 days at $FiO_2 > 0.6$, $p < 0.05$) and lost more weight (6.3 ± 9.2 kg vs 0.75 ± 5.8 kg, $p < 0.05$) than patients with mild airspace enlargement.

Discussion: Histologic lesions characterizing lung barotrauma consist of pleural cysts, bronchiolar dilatation, emphysema-like lesions and intraparenchymal pseudocysts. Mechanical ventilation could be a causative factor, particularly when high peak airway pressures and large tidal volumes are delivered to the lungs.

A.182

COMPARAISON OF PRESSURE SUPPORT VENTILATION PROVIDED BY TWO ICU VENTILATORS

Kalfon P., Rouby J.J., Viars P.

Département d'Anesthésie-Réanimation.
GH Pitié-Salpêtrière Université Paris VI, France

Introduction: Quality of pressure support (PS) ventilation provided by the CESAR ventilator (TAEMA, France) and by the BIRD 8400 ST ventilator (BIRD, USA) were compared.
Patients and methods: Four patients in the process of weaning from mechanical ventilation were studied. For each ventilator, at 4 PS levels (+ 5, + 10, + 15, + 20 cmH20), and for the same trigger (- 1 cm H20), tidal volume (Vt), gas flow (V), esophageal pressure (PES), intratracheal pressure (PAW), and pressure in the ventilator (PV) were recorded. The following parameters were measured : delay between the beginning of inspiration and the time when PV becomes positive (Tor), negative peak pressure of PV, trigger value (Pt), delay between valve opening and obtention of a PV-plateau (Tpl), PV-plateau (Ppl), end-inspiration PAW value (Paw), PAW value at the obtention of the PV-plateau (Pawpl), inspiratory total tidal volume (Vti), inspired volume at the obtention of the PV-plateau (Vtipl), and maximal inspiratory flow (Vmax).
Results: Tor was shorter with the BIRD (98 $^+$ 22 ms) than with the CESAR (162 $^+$46 ms), whatever the PS level. Pt was less negative with the BIRD (- 1.54 $^+$ 0.4 cm H20) than with the CESAR (-2.2 $^+$0.5 cm H20). Ppl differed from the selected PS level : superior with the BIRD, inferior with the CESAR. Tpl was longer with the BIRD than with the CESAR. With both ventilators, no PAW plateau was identified. PAW was close to Ppl for both ventilators, but Pawpl and Pawpl/Paw were higher with the BIRD than with the CESAR. Vti was superior with the BIRD than with the CESAR. Vti and Vtipl/Vti were higher with the BIRD than with the CESAR, whatever the PS level.
Conclusion: Quality of the PS ventilation was evaluated according to 3 criteria : 1) concordance between the selected PS level and the delivered PS level. 2) quality of the inspiratory valve, appreciated by the opening delay and the negative peak pressure in the ventilator. 3) respective aspects of pressure curves in the ventilator and in the trachea. The application of these criteria showed that PS provided by the BIRD ventilator was slightly better than PS provided by the CESAR ventilator. However, with both ventilators, no plateau was obtained within the trachea. A standardization of the evaluation procedures of PS ventilation should permit an accurate comparison of the different avalaible ICU ventilators.

A.183

EVALUATION OF CARDIAC FUNCTION IN ICU : RIGHT HEART CATHETERIZATION *VS* TRANSESOPHAGEAL ECHOCARDIOGRAPHY

Preliminary results

Benoît Vivien, Eric Mourgeon, Michel Saada, Jean-Pierre Goarin, Jean-Jacques Rouby, Pierre Viars

Département d'anesthésie-réanimation, Groupe Hospitalier Pitié-Salpêtrière, Université Paris VI, France

Background and goal of the study: Pulmonary artery catheterization (PAC) is commonly used in ICU to evaluate the hemodynamic status of unstable patients. Recently, transesophageal echocardiography (TEE) has been introduced in ICU for the same purpose. Thus, we prospectively compared both techniques for assessment of hemodynamically unstable patients.
Material and methods : Eighteen consecutive patients admitted in ICU were included. Mean arterial, pulmonary arterial, and capillary wedge pressures, systemic resistance, and cardiac output were obtained using PCA. TEE gave informations on preload (derived from end-diastolic area) and left ventricular (LV) function (derived from LV ejection fraction and LV wall thickening). PAC and TEE were performed and analyzed by 2 different highly-trained experts blinded from each other about their respective hemodynamic evaluation. The following hemodynamic diagnosis could be made : 1) hypovolemia or normovolemia 2) decreased or normal LV function.
Results: Concerning volemia, PAC and TEE concorded in 11 cases. In 5 cases, TEE diagnosed hypovolemia whereas the patients were considered normovolemic by PAC Reciprocally, 2 cases were considered normovolemic by TEE whereas hypovolemia was diagnosed by PAC. The discordance was thus 39% for estimating volemia. Concerning LV function, PAC and TEE concorded in 14 cases. In the remaining 4 cases, TEE diagnosed a decreased LV function whereas it was considered normal by PAC. No patient who exhibited a decreased LV function by PAC was found to have a normal LV function using TEE. The discordance was thus 23% for estimating LV function. Beside this comparison, TEE brought new diagnostic elements in 11 cases: segmental wall motion abnormalities (n=9), mitral cordage dysfunction (n=1), right ventricular pseudoaneurysm (n=1), and voluminous pleural effusion (n=2).
Conclusion : Since TEE is considered to be the gold standard for the assessment of preload and global LV function, this study showed that PCA may be inaccurate in 39% of cases for the assessment of volemia, and in 23% of cases for the assessment of LV function in ICU hemodynamically unstable patients.

A.184

INFLUENCE OF NOREPINEPHRINE THERAPY ON THE OXYGEN SUPPLY AND LACTATE EXTRACTION RATE OF THE LIVER IN THE SEPTIC PIG

Reiner Schäfer*, Werner Gerling*, Angela Utschakowski+, Klaus Wagner#

*Klinik f. Anästhesiologie, +Klinik f. Chirurgie, #Inst. f. Physiologie, Medizinische Universität Lübeck, W-2400 Lübeck, Bundesrepublik Deutschland

Background and goal of study: Little is known about oxygen delivery and consumption in the septic state under experimental conditions in animals, if circulation is hold up as it is done in human patients, i.e. with therapy like norepinephrin and volume. Therefore this study was performed to investigate the influence of norepinephrine in the treatment of the early septic shock on the oxygen consumption and function of an important organ like the liver.

Materials and methods: After government approval we used 16 female domestic pigs between 20 and 28 kg body wt.; 6 pigs without sepsis served as control group. Anesthesia was induced by ketamin/diazepam and maintained by thiopental, fentanyl and pancuronium. Sepsis was induced by E.coli.-endotoxin (0.25-0.5 µg/kg bw, 0.025µg/kg bw/min; infusion was stopped at PAP>60mmHg) and treatment with norepinephrine (0.1 - 2µg/kg bw/min by perfusor) was performed until MAP was >80mmHg. Central venous pressure was held between 5 and 10 mmHg by infusing ringer lactate and/or hydroxyethylstarch. The following values were measured before and after induction of sepsis: Cardiac output (CO, thermodilution), MAP, PAP, A.hep.flow, V.porta flow (electromagnetic/doppler-ultrasound flow probes), systemic and hepatic oxygen consumption, liver tissue pO_2 (needle electrode, polarographically) and lactate extraction rate. Measuring cues were before, 20, 40, 60, 90 and 120 min after induction of sepsis.

Results and discussion: Sepsis treated with Norepinephrin increased CO to 137 % of control, SVR decreased to 64 %. Systemic oxygen consumption increased to 126 %, liver oxygen consumption rested 95% of control values. The flows of the hepatic artery increased to 146 %, whereas the flows of the portal Vene decreased to 63 % of control. The ratio Flow hepatic artery/CO remained constant (about 9 %) throughout sepsis whereas portal venous flow/CO decreased. Liver tissue pO2 remained stable at 35 mmHg. Lactate extraction rate remained also stable at 0.45 mmol/100g liver tissue/min..

Our results suggest that treatment of early sepsis by norepinephrine does not influence oxygen delivery and consumption. The ability to extract lactate is also not depressed. The decrease of portal venous flow perhaps induced by alpha-receptor agonism in the splanchnic circulation is balanced by an increased oxygen extraction and a greater arterial oxygen delivery. The effectiveness of this mechanism is also supported by the stability of the tissue-pO_2-levels. Hepatic arterial vessels seem not to be influenced by norepinephrine.

A.185

THE EFFECT OF DOBUTAMINE AND NOREPINEPHRINE ON GLOBAL AND SPLANCHNIC O_2 CONSUMPTION

Andreas Meier-Hellmann, Lutz Hannemann, Daniel Weyandt,Wolfgang Heiss-Dunlop, Konrad Reinhart

Dept. of Anesthesiology and Surgical Intensive Care Medicine, Steglitz Medical Center, Free University Berlin, FRG

Background and goal of study: Dobutamine (DOB) alone or in combination with norepinephrine (NE) is considered to achieve higher O_2 transport (DO_2) levels and better tissue oxygenation than norepinephrine alone in patients with septic shock, . To prove this we investigated the effect of these two regimens on DO_2, whole body oxygen uptake (VO_2) and splanchnic perfusion (HBF) as well as splanchnic O_2 uptake (VO_{2hep}).

Materials and methods: After approval by our local ethics committee and after obtaining informed consent, 10 patients with septic shock needing inotropic support and vasopressors despite adequate volume loading (PCWP >15 mmHg)were investigated. A 7.5 F catheter was inserted into the hepatic vein. 6 patients were initially treated with DOB combined, if necessary, with NE titrated to maintain a mean arterial blood pressure (MAP) above 70 mmHg. At 0, 60 and 120 minutes, hemodynamic measurements including the oxygen transport related variables and hepatic venous O_2 saturation were performed. Hepatic blood flow (HBF) was determined by the ICG dilution technique. After two hours the regime was changed to NE alone (in a dosage to achieve the same MAP as before), thereafter the same measurements as before were performed. The remaining 6 patients were managed in the reverse order. Statistics: Wilcoxon test for dependent samples ($p < 0.05$).

Results and discussion: The results are given in the table.

	DOB/NE	NE	
DO_2 ml/min/m^2	796 ±151	598 ±113	*
VO_2 ml/min/m^2	159 ±27	152 ±26	n.s.
CI l/min/m^2	6.0 ±1.2	4.3 ±0.8	*
DO_{2hep} ml/min/m^2	210 ±108	171 ±88	*
VO_{2hep} ml/min/m^2	77 ±41	72 ±21	n.s.
HBF l/min/m^2	1,6 ±0.8	1.1 ±0.6	*
DO_2 / DO_{2hep}	4.3 ±1.4	4.1 ±1.7	n.s.
VO_2 / VO_{2hep}	4.9 ±2.5	4,8 ±1.3	n.s.
CI / HBF	4.3 ±1.4	4.1 ±1.7	n.s.
SvO_2 %	76 ±4	71 ±6	*
$ShvO_2$ %	58 ±13	49 ±15	*

CI: cardiac index, SvO_2: mixed venous O_2 saturation. $ShvO_2$: hepatic venous O_2 saturation, * : $p < 0,05$, n.s.: not significant, values are given as mean ± SD

The parallel decrease in DO_2 and DO_{2hep} did not result in a decreased VO_2 and VO_{2hep}. This indicates that oxygen consumption did not become supply dependant in the whole body or the splanchnic region. The unchanged CI/HBF indicates that there was no redistribution of blood flow at the expense of the splanchnic region. We conclude that whole body and splanchnic tissue oxygenation was not compromised with NE alone. The decrease in DO_2 and DO_{2hep} was compensated for by an increase in O_2 extraction.

A.186

INFLUENCE OF N-ACETYLCYSTEINE ON O_2 CONSUMPTION AND GASTRIC INTRAMUCOSAL PH IN SEPTIC PATIENTS

C. Spies, I. Witt, C. Walensky, L. Hannemann, K. Reinhart

Department. of Anesthesiology and Intensive Care Medicine, Steglitz Medical Center, Free University Berlin, Berlin, Germany

Background and goal of study: Endothelium-derived relaxing factor (EDRF) might be important in maintaining microcirculatory blood flow in critically ill patients but its full activity might not be sustained because of the depletion of tissue sulhydryl groups. N-acetylcysteine (NAC) by replenishing tissue sulfhydryl groups could restore the full activity of EDRF. We investigated whether NAC would be of benefit in septic patients with multiple-organ failure.
Materials and methods: 38 septic patients, requiring extended hemodynamic monitoring (radial and pulmonary artery catheter) were included in this randomized, institutionally approved study. A gastric tonometer was inserted to assess nutritive blood flow to the mucosa by measuring gastric intramucosal pH (pHi). Written informed consent was obtained from the relatives. Patients received either 150 mg/kg NAC or placebo over a period of 20 minutes. Measurements were obtained before treatment (baseline), after 30 minutes of infusion (infusion), and 2 hours after infusion (recovery). Statistical analysis was performed by the Wilcoxon signed rank-sum test and adjusted for Bonferroni's method.
Results and discussion: Baseline and recovery measurements were not significantly different between groups. After infusion of NAC O_2 consumption (VO_2), O_2 delivery (DO_2), cardiac index, and O_2 extraction ratio (O_2ER), as well as pHi significantly increased in 9 patients of the NAC group (responder). In the other 10 patients of the NAC group (non-responder) as well as in the placebo group all parameters remained stable. In the NAC group 11 patients, in the placebo group 5 patients survived.
Conclusion: Some patients showed an improvement in VO_2, O_2ER, and pHi after NAC infusion which might be consistent with an improvement in microcirculatory blood flow. Whether survival is improved requires further investigation.

MOLECULAR MEDIATORS AND POST-BACTERAEMIC PHASE

K Martínez Urionabarrenetxea, JL Pérez Arancón, JI Yoldi, A Camarero, JL Martínez

Intensive Care Units, Hospital de Navarra, Pamplona, Spain

INTRODUCTION.- It is well known that TNF acts as a mediator in shock and organ disfunction during sepsis(1). Its metabolism makes its study difficult in non-shocked septic patients (2). This prospective study was performed to evaluate changes in blood levels of TNF and PAI-1 in post-bacteriemic states.

METHODS.- Twenty patients, who accomplised inclusion criteria as septic were studied. Inclusion criteria were: evidence of septic focus; no bacteriemic sign two hours before blood extraction; hemodynamic stability; leukocytosis and/or inmature leukocytes. Mean organ disfunction was 3 organs, extremes ranging from 2 to 6.

To estimate the variability of TNF and PAI-1 values, a group of 24 volunteers during their usual work was analyzed.

RESULTS.- The analysis of TNF and PAI-1 values in patients related to controls shows significant difference for both mediators.

TNF	**Mean±St Error**	p
Controls	1,62±0,44	
Patients.	55,09±1,44	0,001

PAI-I	**Mean±St Error**	p
Controls	14,16±1,56	
Patients	19,86±1,91	0,05

COMMENTS.- Monocytic system reponds to infection intensely producing TNF during the two first hours, to saty refractary to new stimuli for the next 8 hours, but with slighlty high levels. The endotehlium is stimulated by TNF to release PAI-1, which reaches peak level 3 hours later and returns to basal values in 24 hours.

This study shows elevations of TNF during the refractary period and of PAI-1 before the 24 hours after the bacteriemic phase.

CONCLUSIONS.- TNF and PAI-1 are indicators of infection in the post-bacteriemic phase.

MOLECULAR MEDIATORS AND CARDIAC SURGERY

**JL Pérez Arancón, K Martínez Urionabarrenetxea,
JI Yoldi, A Camarero, JL Martínez**

Intensive Care Units, Hospital de Navarra, Pamplona, Spain

INTRODUCTION.- It is well known that infection induces the release in plasma of high levels of TNF and other cytokines. TNF itself stimulates the release of PAI-1, which may independently reach very high levels in any inmediate post-surgiral state.

The elevation of TNF and PAI-1 blood levels in patients with no infectious pathology undergoing cardiac surgery has been described, thus invalidating these parameters as diagnostic data of infection in these patients.

This prospective study was performed to evaluate changes in plasma concentrations of TNF and PAI-1 in patients undergoing open heart surgery.

METHODS.- Twenty patients undergoing open heart surgery with extracorporeal circulation, and who accomplished inclusion criteria as non septical were studied.

To estimate the variability in TNF and PAI-1 plasma levels, a group of 24 volunteers in their usual work was analyzed.

Inclusion criteria were: absence of infection; no evidence of septic focus; subsystems'stability; no leukocytosis and/or leukopenia.

RESULTS.- The analysis of TNF and PAI-1 values in surgical patients related to controls shows significant difference for both mediators.

TNF	Mean±St Error	p
Controls	1,62±0,44	
Pat. Art.	72,06±26,08	0,001
Pat. Ven.	65,36±21,37	0,001

PAI-I	Mean±St Error	p
Controls	14,16±1,56	
Pat. Art.	21,31±2,16	0,01
Pat. Ven.	21,36±2,1	0,05

No significant difference was found between arterial and venous TNF and PAI-1 levels in the patient group.

CONCLUSIONS.- High levels of TNF and PAI-1 in inmediate extracorporeal cardiac surgery are not suggestive of infection.

Absence of arterio-venous differences in the values of both mediators is an indirect parameter of metabolic normality.

A.189

SEPTIC SHOCK : EFFECT OF A GOAL-DIRECTED THERAPY ON OXYGEN METABOLISM AND SERUM CYTOKINE LEVELS

Claude MARTIN, Pierre SAUX, Jean-Louis MEGE,
Gilles PERRIN, François GOUIN

Department of Anesthesia and intensive Care.
Hôpital Nord and Hôpital Sainte-Marguerite
13009 MARSEILLE - FRANCE

Background and goal of study : achieving and maintaning optimal hemodynamic and metabolic patterns have been suggested to improve survival of critically ill septic patients (1, 2). The present study was designed to prospectively evaluate the effects of such a goal-directed therapy on oxygen-derived parameters (Oxygen delivery - DO2, Oxygen uptake - VO2) and serum cytokine levels in septic shock patients.

Materials and methods : thirty consecutive patients (56 ± 20 years, APACHE II Score 31 ± 1) were prospectively studied. All patients were mechanically ventilated for ARDS or severe pneumonia. Different modes of therapy (fluid loading, dobutamine, norepinephrine and dopamine) were used to achieve and maintain at the same time all of the following : Mean Systemic Arterial Pressure ≥ 80 mmHg (and/or Systemic Vascular Resistance Index between 1,100 and 1,300 dyn.sec/cm5.m2), IDO2 ≥ 550 ml/min/m2, IVO2 ≥ 150 ml/min/m2 and Cardiac index ≥ 4.0 l/min/m2. The aim of therapy was to fullfilled these previously determined goals for at least 24 hours and to restore and maintain normal urine flow (≥ 0.7 ml/kg/h whenever possible). Hemodynamic and oxygen derived parameters were checked every 4 hours and therapy was reevaluated according to the therapeutic goals. Serum lactate and cytokine (TNFα and IL6) levels were also determined. The predicted mortality was obtained using the APACHE II scoring system.

Results and discussion : The therapeutic goals were achieved and maintained for at least 24 hours in all but two patients (93 %). Twenty four patients (80 %) survived the episode of septic shock and 6 (20 %) died in intractable shock. Nine patients subsequently died from Multiple Organ Failure and 15 patients were eventually discharged from the hospital. The overall hospital mortality (50 %) was significantly lower than the APACHE II predicted mortality : 80 % (p <0.02). The table shows that in the survivors (S) a significant increase in IDO2 and IVO2 was observed throughout the first 24 hours. No such improvement was seen in patients who died in shock (D) or from organ failure (MOF). lactate levels exhibited a significant decrease from the 6th hour on, only in survivors and MOF patients Serum TNF levels exhibited a significant decrease from the 6th hour on, only in the survivors. In MOF patients, serum TNFα levels remained elevated which was in contrast with the improvement observed in their hemodynamic condition and serum lactate levels. A similar and progressive decrease in serum IL6 levels was observed in the three groups.**Conclusion :** An improvement of oxygen utilization was seen only in survivors. The decrease in serum TNFa levels was significantly associated with a favorable outcome. Moreover, a goal-directed therapy aimed at improving hemodynamic and metabolic conditions of septic shock patients may substancially reduce mortality **References :** 1. Chest 94:1176-1186, 1988 2.Crit Care Med 17:1098+1103, 1989

A.190

COMPARISON OF TWO THERAPEUTIC STRATEGIES OF SEPTIC SHOCK

Claude Martin, Jean-Pierre Auffray, Frédéric Potié,
François Gouin.

Hôpital Nord et Hôpital Sainte-Marguerite
Marseille - France

Background and goal of study : the optimal therapy of septic shock remains a matter of controversy.
Materials and methods : from january 1988 to january 1992, two therapeutic strategies were prospectively evaluated in 129 patients with septic shock. In group 1 (72 patients) all patients had a Swan-Ganz catheter and an arterial catheter inserted. Hemodynamic parameters (measured and calculated), oxygen-derived parameters (oxygen delivery - IDO2 - and uptake - IVO2), blood lactate, arterial and mixed-venous blood gas analysis were obtained every 4 hours (or more when needed). Based on the results, appropriate treatments (fluid infusion, vaso-active agents) were selected and the goals were to achieve and maintain all of the following : cardiac index ≥ 4 l/min/m2, vascular resistance > 1100 dyne.sec/cm5.m2 and / or mean arterial pressure (MAP) ≥ 80 mmHg, IDO2 > 550 ml/min/m2, IVO2 > 150 ml/min/m2, urinary flow (UF) ≥ 0.7 ml/kg/h. In group 2 (57 patients) patients had a central venous line and an arterial catheter inserted. Vital signs were obtained every hour. The aim of therapy was to achieve and maintain MAP ≥ 80 mmHg and UF ≥ 0.7 ml/kg/h. In both groups, patients were mechanically ventilated and SpO2 was maintained > 95%. The choice of therapy was based on the physician's preference.
Results and discussion : both groups were similar with regard to : age (56 ± 17 and 58 ± 17 years), sex-ratio (males : 75% and 68%), APACHE II score (29 ± 3 and 27.5 ± 3), peritonitis (35% and 40%), pneumonia (53% and 47%), appropriate antibiotic therapy (80% and 70%), dobutamine (60% and 58%). More patients received norepinephrine in group 1 (100% vs 58%, p < 0.01) and dopamine in group 2 (65% vs 36%, p < 0.01). Therapeutic goals were simultaneously fulfilled for 24 hours in 92% of patients in group 1. In group 1, hospital mortality was 53% and 86% in group 2 (p < 0.001).
Conclusion : the present study was neither blinded nor randomized.However, the results suggest that a goal-directed therapy based on hemodynamic and metabolic parameters may significantly reduce hospital mortality of patients with septic shock.

A.191

NON INVASIVE MONITORING OF CO_2 IN PATIENTS WITH SEPTIC SHOCK

L. Bodin, H. Maghrebi, C. Kaddour, M. Arthaud,
J.J. Rouby, P. Viars.

Département d'Anesthésie–Réanimation GH Pitié–Salpêtrière.
Université Paris VI. France

Introduction : Two methods are available for $PaCO_2$ monitoring : end–tidal carbon dioxyde tension (Pet CO_2) and transcutaneous CO_2 (Ptc CO_2). The aim of this study was to evaluate capnometry and transcutaneous CO_2 monitoring in critically ill patients with septic shock and ARDS.
Methods: Seven critically ill patients with septic shock and ARDS were prospectively studied. Patients with brain injury, pulmonary embolism, or coronary artery disease were excluded. $PaCO_2$ was measured using a Blood Gas Analyser. Pet CO_2 was measured using a non aspirative capnometer (Hewlett–Packard HP 47210A). Ptc CO_2 was measured using a Critikon Fas–Trac and a sub–clavicular probe. Every 6 hours, calibration was performed and the site of the probe was changed. For each patient, 3 tidal volumes (VT) of 5,10 and 14 ml/kg were randomly applied in order to modify $PaCO_2$. Seventy simultaneous measures of $PaCO_2$, Pet CO_2 and Ptc CO_2 were performed after a steady state was obtained for a given VT. Differences between $PaCO_2$ and Pet CO_2 and between $PaCO_2$ and Ptc CO_2 were calculated for the different values of $PaCO_2$. Bias and precision determinations were calculated using the method of Bland and Altman (1).
Results: Results are shown on figures 1 and 2. Bias and precision were respectively of – 9 mmHg and 6 mmHg for the capnometer and of – 2.5 mmHg and 2.7 mmHg for the Ptc CO_2.
Discussion : This study shows that in patients with septic shock, Ptc CO_2 remains an accurate method for monitoring $PaCO_2$. In contrast, Pet CO_2 markedly underestimates $PaCO_2$.

A.192

EVALUATION OF SYSTEMATIC TEE IN PATIENTS SUSPECTED OF BLUNT CHEST TRAUMA.

P.Catoire*, L.Delaunay*, L.Beydon*, P.Guerrini*, F.Bonnet*.

*Réanimation chirurgicale, hôpital Henri Mondor, CRETEIL; FRANCE.

Background and goal of the study: Intra-thoracic lesions can be missed after blunt chest trauma (BCT) because appropriate diagnostic tools are invasive and therefore can not be systematically used. TEE is a non-invasive technique allowing the diagnosis of intra-thoracic lesions in a selected population of patients with widening of the mediastinum on chest X-ray after blunt chest trauma (1). We carried out a prospective study in order to evaluate TEE in patients suspected of BCT.

Material and methods: Thirty six patients were included in this prospective study. Patients suspected of BCT because of a violent shock, a rapid deceleration after a traffic crash or a fall, were scheduled for TEE. All of them were intubated, under controlled ventilation. We used a Diasonics ® CFM 750 echocardiograph with a 5 MHz transesophageal probe. TEE examination was performed within 48 hours following admission. The results of TEE were compared to informations obtained on admission from clinical examination, chest X-ray, 12 leads ECG and CK-MB plasma concentrations.

Results and discussion: Patients mean severity score index was 31±11. None of the patients had a significant cardiac enlargement on chest X-ray. Myocardial contusion was suspected in 14 cases (12 ECG abnormalities, 3 increases in CK-MB). TEE docu-mented segmental wall motion abnormalities or altered global function in 8 patients (22%). In addition, TEE found out unexpected thoracic lesions in 11 patients (30%) including 8 pericardial effusions, one tricuspid and one mitral valve regurgitation, and one ascending aortic intimal tear. Four of these patients had no clinical evidence for chest trauma. In three patients, severe hypovolaemia was asserted (ITDA≤ 5cm^2). Moreover, 9 pleural effusions and 5 lung conden-sations were documented on TEE and confirmed by CT scan. TEE diagnosis allowed an immediate specific treatment in 5 cases leading to a dramatic inprovement of patients condition.

Conclusion: TEE must be systematically performed in multiple trauma patients when BCT is suspected. It allows to discover intrathoracic lesions which may justify an appropriate treatment in a significant number of cases.

DIAGNOSIS OF AORTIC RUPTURE BY TRANSESOPHAGEAL ECHOCARDIOGRAPHY (TEE)

J.P. Goarin, F. Le Bret, Y. Jacquens,
B. Riou, M. Saada, P. Viars
Department of Anesthesiology.
CHU Pitié-Salpêtrière. Paris. France

Backgrounds and aim of the study. Blunt chest trauma, occurring during high-speed deceleration accidents, can be associated with aortic rupture. Prognosis depends on prompt diagnosis and surgical treatment. Angiography is the routine procedure, nevertheless this method is time consuming, invasive and can be hazardous for patients with multi system injuries and unstable hemodynamic status. Some studies have demonstrated the accuracy of TEE for spontaneous aortic dissection diagnosis (1). The aim of this study is to evaluate TEE in traumatic aortic lesion.

Patients and methods. TEE was performed in all patients with blunt chest trauma to assess the hemodynamic status and to detect intra-thoracic lesions (aortic rupture, myocardial contusion, pericardial, mediastinal and pleural effusions). We used a Hewlett-Packard Sono S500 with a single plane transesophageal probe. TEE were recorded on video-tape for retrospective cross examination by an undependant observer. The results were compared with angiographic and intraoperative findings.

Results. During a 26 months period, 37 patients had both TEE and angiography.

8 presented a traumatic aortic lesion : 5 had a false-aneurysm localized to the isthmus, associated for 3 of them, with a dissection of descending aorta. 3 patients had a rupture limited to the intimal part of the aortic wall.The diagnosis could have been made immediately in 6 cases and in one more case after reviewing the video-tape. In one case TEE was considered normal. Angiography and TEE were confirmed by operative findings.

TEE Angio	Positive	Negative	Uncertain*
Positive	6	1	1
Negative	0	28	1
Uncertain	0	0	0

* The diagnosis was considered uncertain when the examiner and the independent observer disagreed.

Conclusion. Sensitivity and specificity is hard to define on a retrospective study but we can conclude already that TEE can provide (6/8 cases) a rapid diagnosis of aortic rupture with no need for further investigation in emergency situation.

SYSTEMIC GAS EMBOLISM IN PULMONARY CONTUSION DIAGNOSED BY TRANSESOPHAGEAL ECHOCARDIOGRAPHY

Michel Saada, Bruno Riou, Jean-Pierre Goarin,
Jean-jacques Rouby, Yves Jacquens, P. Viars.
Department of Anaesthesiology,
CHU Pitié-Salpêtrière, Paris, France

Background: Systemic gaz embolism has been described following penetrating lung injury (1) and acute respiratory distress syndrome (2) in adults and children, but has never been reported in pulmonary contusion related to severe blunt trauma. We observed 4 patients with suspicion of systemic gas embolism following severe blunt thoracic trauma induced pulmonary contusion. Two out of 4 were demonstrated by transesophageal echocardiography (TEE). We report in the following abstract one of these 4 patients.

Patients and methods: A 27 y.o. man was admitted in a level 1 Trauma Center after a motorcycle accident. On arrival, the patient had complete paraplegia secondary to spinal cord injury at T4 level, thoracic trauma with multiple rib fractures and pulmonary contusion, and left leg fracture. During peripheral orthopedic surgery, severe hypotension was noted, associated with a significant decrease in SaO2 and endtidal CO2. Fat embolism was suspected and TEE was performed which showed a normal global and segmental left ventricular function and massive air embolism in the left heart coming from the pulmonary veins and rythmed by mechanical ventilation. During apnea, no more bubbles were observed. Patients recovery was complete without neurologic sequelae secondary to gas embolism.

Discussion: Systemic gas embolism can occur after sever pulmonary contusion and its incidence is probably underestimated. It can be aggravated during mechanical ventilation due to overdistension of the lung secondary to large tidal volume, resulting in an interstitial and alveolar edema and ruptured capillaries. Such events may happen during mechanical ventilation in patients with pulmonary contusion.Thus it should be recommanded to reduce tidal volume, to avoid PEEP, and possibly to use high frequency Jet ventilation in order to decrease the mean airway pressure.

THE CHOICE OF ECM RATE COULD IMPROVE THE NEUROPROTECTION DURING CPR

E.Iannuzzi, E.De Blasio, F.Ferraro, A.De Sio, F.Schiraldi
Cattedra di Anestesia e Rianimazione (dir. GF. Mostarda)
Medicina e Chirurgia II Ateneo Università di Napoli Italia

Introduction: Recent CPR guidelines (1) emphasize the importance of optimizing the external cardiac massage (ECM) rates in order to improve oxygen tissue delivery and acid product removal. We recently found that faster ECM rates improve cardiac output significantly but not $S\bar{v}O_2$ (2). Since the main aim of CPR is to maintain adequate coronary perfusion and cerebral blood flow (CBF),we investigated some metabolic/perfusional aspects of slower and faster MCE rates.

Methods: In 6 critically ill patients, needing CPR, a catheter was placed in the jugular bulb within the first minute of the circulatory arrest; the ECM was randomly performed in 3 patients at 80/m' for 3 m' followed by 130/m' for the next 3 m'; in the other 3 patients the sequence of ECM rates was inverted. At the end of each 3 m' period, samples of arterial, mixed venous and jugular venous blood were drawn for gas-analysis. The data collected were analysed using the T-Student test.

Results: Faster ECM rates were able to significantly improve $SjvO_2$, indipendent of the VSO_2 behaviour; besides the $\Delta CO_2a\text{-}jv$ at 130/m' was narrower than the $\Delta CO_2a\text{-}jv$ at 80/m' and than the $\Delta CO_2a\text{-}\bar{v}$ demonstrating a higher capacity of waste product removal.

ECM rates	130	80
SaO_2	84.2±20.4	78±25.3
$S\bar{v}O_2$	24.6±9	15.3±10.5
$SjvO_2$	36.1±11.2 ①	17.4±10.8
$\Delta Sa\text{-}\bar{v}O_2$	59.6±12.9	62.7±18.4
$\Delta Sa\text{-}jvO_2$	48.1±13	60.4±17.9
$\Delta CO_2\bar{v}\text{-}jv$	16.4±16.9	3.25±7.8
$PaCO_2$	47.2±20.9	45.3±20.2
$P\bar{v}CO_2$	83.4±35.9	88.3±34.5
PjO_2	67.0±27	85.1±37.7
$\Delta CO_2a\text{-}\bar{v}$	36.2±21.7	43±15.4
$\Delta CO_2a\text{-}jv$	19.8±8.3 ②	39.7±20.2
$\Delta SjvO_2$	11.5±3.4 ③	2.23±2.8
① $p<0.02$	② $p<0.05$	③ $p<0.001$

Conclusions: CPR with ECM rates >100/m' seems to improve C.O. and CBF allowing a better neuroprotection during the period of circulatory arrest.

HELICOPTER TRANSPORTATION OF PATIENTS WITH SYMPTOMATIC AORTIC ANEURISMS

P. Felleiter, W. Breschinski, K. H. Bock

Dept. of Anaesthesiology and Intensive Care Medicine
Federal Armed Forces Hospital, Ulm, Germany

Background and goal of study. Helicopter transportation of patients with aortic aneurisms differs from most other interhospital transports. Therefore we investigated which specialties have to be expected, what kind of complications do arise and which measures can be taken to avoid them.

Methods. We retrospectively analyzed the patients transported with the Ulm-based rescue helicopter between March 1986 and February 1992. Data of 24 patients with symptomatic aortic aneurisms were taken from transport and helicopter protocols. Patients were divided into two groups, depending on whether the aneurism was ruptured or not. Complications were registered using a list of incidents liable to arise during the transportation of patients.

Results. In 42 % of the patients rupture of an aortic aneurism was diagnosed before the beginning of transportation. Systolic blood pressure was lower in patients with ruptured aneurisms ($p < 0.05$), less then 80 mm Hg were measured in 60 % of these patients at the beginning of transportation. These patients also received more infusion volume during the transportation ($p < 0.01$), but even combining volume replacement with the use of the medical anti shock trousers (70 %) and the application of positiv inotrope drugs (40 %) could not prevent that 44 % of these patients still had a systolic blood pressure of less then 80 mm Hg at the end of transportation. In the group of patients with non-ruptured aortic aneurisms, hypertension had to be treated in 50 % of the cases. In more than half of the patients with ruptured aortic aneurisms, accompanying physicians did see the necessity to place additional intravenous catheters (60 %) and/or to intensify the volume replacement therapy (70 %) before transportation could be started. No patient died during the transportation, complications did arise in two cases (8.3 %).

Conclusions. During secondary transportation of critically ill patients it is imperative to maintain the monitoring of vital functions, to continue the adequate therapy and to ensure that intervention by an accompanying physician is possible, when complications should arise. Transportation of patients with ruptured or non-ruptured aortic aneurisms requires great care in preparation as well as performance by both clinical and rescue teams. Treatment of hemorrhagic shock has priority for patients with ruptured aneurisms, whereas it is most important for patients with non-ruptured aneurisms to prevent rupture by careful handling and immediate treatment of hypertension.

A.197

THE PART OF RESCUE HELICOPTERS IN LARGE ACCIDENTS AND DISASTERS

Wenker Olivier
Medical Department, Swiss Air Rescue REGA,
Zürich, Switzerland

Background: Even if an helicopter is a multi-purpose flying machine, in the planning of rescue and disaster operations he is mostly only used as a transport facility for the injured. Nevertheless there were various functions that he could fulfill in the course of a rescue action at disasters as shown in the following

Mission possibilitys: *Search and supervision from the air:* Often there is some unclearness concerning the exact localization about the scene of accident. Air-search (as far as the weather allows it) is fast and effective. During the night may be used additionally special spotlight detectors. Beneath exact coordinates may also be transmitted to the operational base informations about the traffic density, additional dangerness and geographical qualitys of the accident place. This allows a better survey and therefore a more specific planning of the operational rescue work. *Staff and life-saving equipements:* Additional staff and special life-saving equipements can be delivered as fast as possible to the scene of accident. *Salvage operations:* In certain situations a helicopter lasts the only possibility of rescue. A cable-winch allows it either to set down a medical doctor and other staff at an impassable area or to rescue injured people carefully. There is also a big advantage in the search and rescue of shipwrecked persons and the evacuation of endangered persons from roofs during a fire. *Support of special rescue-troops:* Fire-fighters with special respiratory-support can be roped down on roofs. Divers can be brought fast to an accident-area in the water. At forest-fires some air-operated support for the extinguishing work may also be very helpful. At avalanche-accidents and landslips the discovery of buried persons can be pushed ahead by air-tranportation of special localizers and dog-teams. *Patient transport:* At larger accidents the optimal care of single patients inevitably brings up some difficulty. The evacuation of injured persons can be supported by air in the course of which should be aimed at a far-reaching evacuation. *Secundary transports:* Large-range transfers can help to avoid defiles at smaller hospitals. Carefull transports to specialized clinics can be exected and intensive care units can be relieved of postoperative patients.

Discussion: A rescue helicopter is a fast, mobile and versatile usable rescue auxiliary. Concerning larger accidents or disasters the initial functions, such as salvage operations, treatement and transport of single persons stay at least at the beginnig of a rescue operation in the background to enable other just shown assignements.

EVALUATION OF PAIN AND ANALGESIA IN A POSTANESTHESIA CARE UNIT

Frédéric Aubrun, Patrick Narchi, Dan Benhamou

Département d'Anesthésie, Hôpital Antoine Béclère,
Université Paris-Sud, 92141 Clamart, France

Background and goal of study: Systematic and early treatment of postoperative pain is more efficacious than on demand administration (1) and pretreatment with analgesics may result in decreased postoperative pain severity (2). The postanesthesia care unit (PACU) seems therefore the logical place where pain control should start.This study was thus intended to evaluate the degree of pain at arrival and during stay in PACU.

Material and methods: Pain was assessed in our PACU in 100 consecutive adults patients after orthopedic, abdominal or gynacologic surgery. Pain was evaluated by the same observer using a 0-100 mm visual analog pain scale (VAPS) 1) at arrival in the PACU and 2) immediately before patient's discharge from PACU. Pain was classified in 3 categories: minor (≤20), moderate (>20 and ≤ 60) and severe (> 60). PACU nurses were unaware of the VAPS results and used either a slow infusion of propacetamol intravenously (2g) or iv titrated morphine (2-3 mg every 10 min) according to the routine management of pain in our Department. The type of anesthesia (regional or general) and the analgesics administered during surgery were recorded, as well as the duration of stay in the PACU.

Results and discussion: Patients (mean age: 44 ± 17 y.o.) had been scheduled for orthopedic (21%), abdominal (34%), gynecologic (45%) surgery. Anesthesia was regional in 31% of cases. 50% and 58% of patients had moderate or severe pain at arrival and at discharge respectively (figure). 40% of our patients received propacetamol, 6% received iv morphine and 9% received a combination of both drugs. 33% of patients had a higher VAPS value at discharge than at arrival.

Conclusion: Pain was insufficiently treated in our PACU although 55% of patients received analgesics intravenously. A more precise and agressive pain control protocol is required.

ORGANIZATION OF ACUTE PAIN SERVICES - A LOW-COST MODEL

Narinder Rawal

Department of Anaesthesia and Intensive Care, Örebro
Medical Center Hospital, Örebro, Sweden

Despite unprecedented interest in pain and its management, most patients undergoing surgery still receive treatments that have changed little in the past decades. The most common method of managing pain following surgery has been and still is the use of i.m. opioids prescribed on an "as needed" basis. The inadequacies of this method of pain management have long been recognized.

In the United States 24-hour acute pain services are being increasingly established to provide good quality analgesia. Such services usually consist of anesthesiologists, residents, specially trained nurses and pharmacists. The economic costs of such services are high ($200 or more per day per patient) and therefore the benefits not available to all surgical patients because of reimbursement regulations. Simpler and less expensive alternatives have to be developed if the aim is to improve the quality of postoperative analgesia for every patient on the surgical ward. Sophisticated analgesia techniques such as epidural and PCA are neither necessary nor realistic for most patients. Even in hospitals with well functioning acute pain services these techniques are used in less than 20% of all surgical patients.

Our nurse-based-anesthesiologist-supported model is based on the concept that postoperative pain relief can be greatly improved by provision of in-service training for nursing staff, optimal use of systemic opioids and peripherally acting analgesics and use of regional analgesia techniques in selected patients. Regular recording of pain intensity and treatment efficacy are the cornerstone of this model. Every patient who has undergone surgery is asked to grade his or her pain severity on VAS. This is done every 3 h and recorded on a specially reserved place on the bedside vital sign chart. Pain intensity is also scored before and 30-45 min after prescribed treatment. A VAS below 4 is aimed at all times.

A specially trained Acute Pain Nurse makes daily rounds of all surgery departments. Her duties include checking VAS recording on charts, helping with technical problems related to PCA or regional analgesia techniques and referral of problem patients to the anesthesiologist.

Appropriate guidelines regarding dose of analgesia, treatment of inadequate analgesia, patient monitoring, potential complications and their management are provided. Nurse responsibility and physician accountability are also defined. In the organization described above the only additional cost is that of the Acute Pain Nurse. At our hospital about 18000 surgical procedures are performed each year, all these patients can be expected to benefit from this low-cost organization.

A.200

EPIDURAL ADMINISTRATION OF LIPOSOMAL BUPIVACAINE FOR THE MANAGEMENT OF POSTSURGICAL PAIN.

Jean Boogaerts, Noelle Lafont, and Franz J. Legros.
Department of Anesthesiology and Intensive Care, Clinique Reine Fabiola, Montignies-sur-Sambre, Belgium.

Background and goal of study: Encapsulation of bupivacaine into multilamellar liposomes led to a reduction of systemic toxicity (1). Duration and quality of human postsurgical analgesia were compared between plain and liposomal bupivacaine after epidural injection.

Materials and Methods: Ten milliliters of sterile and apyrogenic solutions containing 0.5% bupivacaine, plain (BP; n=12) or encapsulated in multilamellar liposomes made of phosphatidylcholine and cholesterol in a molar ratio 4:3 (L-BP; n=14), were administereed to ASA Class I to III patients undergoing major surgery (abdominal, vascular, urologic, thoracic, orthopedic). One single dose injection was performed after completion of the operation through an epidural catheter inserted during the surgical procedure. The following parameters were measured: duration of analgesia, quality of motor blockade (Bromage scale) and sympathetic blockade (Hypotension). Data were expressed as Mean ± SEM. Significant differences were identified by Student's t test, ANOVA test and Mann-Whitney test.

Results and discussion:

	Analgesia (h)	Motor Block	Symp.Block
BP	3.2±0.4	9 patients	10 patients
L-BP	6.2±1.1*	0*	7 patients

* $p < 0.05$.

The duration of the analgesic action significantly increased from 3.2 to 6.2 hours. No motor block was observed.

Conclusion: The encapsulation of bupivacaine into multilamellar liposomes resulted in a prolongation of its postsurgical analgesic action without motor block.

Reference: 1. Boogaerts J, Declercq A, Lafont N et al. Toxicity of bupivacaine encapsulated into liposomes and injected intravenously. Comparison with plain solutions. Anesth Analg 1993; 75: in press.

A.201

POSTOPERATIVE ANALGESIA: A TWO DOSAGE REGIMENS TRIAL FOR I.M. MORPHINE AFTER EARLY I.V. TITRATION.

Karin Butscher, J.Xavier Mazoit, Kamran Samii

Anaes Dpt, Université Paris-Sud, Hôpital de Bicêtre,
94275 - Le Kremlin-Bicêtre, FRANCE

Background and goal of the study: The wide interindividual variability in analgesic needs often leads to therapeutic failure when opioids are administered systematically (1). The goal of this study was to evaluate the efficacy of two dosage regimens of i.m. morphine after an early i.v. titration in the postoperative period.

Methods: After ethical committee approval, 70 ASA I-II patients scheduled for abdominal, urologic or orthopedic surgery were randomly allocated into two groups. In the recovery room, when complaining, patients recieved morphine hydrochloride 3 mg i.v. every 10 min until satisfactory analgesia was achieved. If the total initial i.v. dose was ≥ 6 mg, analgesia was maintained with i.m. morphine. Group I received 2/3 of the initial i.v. dose 3 hours after the end of titration followed by 1/2 of the i.v. initial dose every 4 hours after. Group II received 1/2 of the initial i.v. dose 3 hours after the end of titration followed by 1/3 of the i.v. initial dose every 4 hours after. Pain was evaluated by visual analog scale, 0-10 cm (VAS). Statistics used semi-parametric analysis of repeated mesures. Data are mean ± SD.

Results and discussion: Twenty patients were excluded: 17 received paracetamol and codeine for maintenance after an initial i.v. dose ≤ 6 mg (n=17), one needed supplemental analgesia, two had sedation or respiratory depression in the recovery room. The total initial i.v. dose was 16.0 ± 6.5 mg (range 9-33 mg). Pain relief was similar in both groups during the first postoperative day (figure).

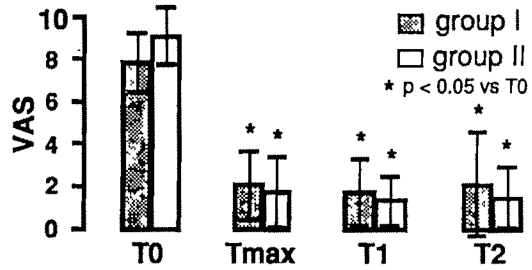

Figure: VAS at T0 = before i.v. titration, Tmax = end of i.v. titration, T1 = before the first i.m. injection, T2 = next morning.

Conclusion: Our study shows that an early titration of i.v.morphine in the postoperative period permits an efficient analgesia with a low dose i.m. maintenance regimen.

A.202

ANALGESIA BY WOUND INFILTRATION BEFORE OR AFTER SURGERY IN INGUINAL HERNIORAPHY

Danielle Hennart, Yves Mersch
Department of Anesthesia, Erasme Hospital, Brussels, Belgium

Background and goal of study: Analgesia given before the painfull stimulus could prevent or reduce susbsequent pain. The aim of this study was to compare the effects of a neural blockade performed either before or after sugery.

Materials and methods: Fifteen male adults, ASA I or II, aged from 18 to 70 years, scheduled for inpatient unilateral inguinal herniorrhaphy were selected for the study after written informed consent. Midazolam 0.1 mg/kg IM was given for premedication. Anesthesia was induced with 2 mg/kg propofol and 0.02 mg/kg alfentanil. The patient's trachea was intubated after the injection of 0.5 mg/kg atracurium, and the lungs were mechanically ventilated with an O2/N2O mixture (FiO2: 0.4). Anesthesia was maintained by a continuous infusion of propofol (6 - 12 mg/kg/hour) and additional boluses of alfentanil (0.01 mg/kg) as needed. All patients had an infiltation of the abdominal wall along the line of the proposed incision 5 min. before surgery and an infiltration of the wound edges just before skin closure. Group A (N=7) received bupivacaine 0.5% before surgery and NaCl 0.9% at the end of surgery; group B (N=8) received NaCl 0.9% before and bupivacaine at the end of surgery. All infiltrations consisted of a volume of 0.25 ml/kg and were made in a double-blind manner. Morphine administered by a PCA pump was used for postoperative analgesia, allowing a precise assessment of the analgesic needs. Each bolus consisted of 2 mg, with a lock-out interval of 10 min and a maximal allowable dose of 20 mg in any 4 hours period. Pain was assessed using VAS at rest, during inspiration, and during cough, 12 hours and 24 hours after the end of surgery. Maximal inspiratory volume using incentive spirometry was measured the day before surgery, and 12 and 24 hours after surgery; patients were asked if maximal inspiration was limited by pain.

Results: Duration of surgery, and the amounts of propofol and alfentanil administered were statistically identical between the groups.

Group	Morph. at 12 H (mg)	Morph at 24 H (mg)	VAS rest 12H	VAS insp 12H	VAS cough 12H	VAS rest 24H	VAS insp 24H	VAS cough 24H
A	25±14	40±18	2 8±1.3	4 6±1.9	6 4±2 6	2.0±1.4	2 7±1.6	6.5±2 7
B	27±14	39±17	1.9±0 8	3.5±1.8	6 8±1.7	1 9±0 8	2 6±1.9	5.1±2 0

There was no statistical difference between the groups in any parameter exposed in the table, or in the maximal inspiratory volumes measured after surgery. Nevertheless, 24 H. after surgery, pain was not a subjective limiting factor in inspiration for any patient in Group A, but it remained a limiting factor for 4 patients in Group B (p=0.07, Fisher test).

Conclusions: Without reducing the amount of morphine needed, the preoperative infiltration with bupivacaine could have favorable effects on patients respiratory confort.

A.203

PREEMPTIVE ANALGESIA WITH EPIDURAL MORPHINE

Isabelle Nègre, Jean Pierre Guéneron, Samir Jamali,
Sylvaine Monin, Claude Ecoffey

Département d'Anesthésie-Réanimation
Université ParisSud, Hôpital de Bicêtre
94275 Le Kremlin Bicêtre Cedex, France

Background and goal of the study: Preemptive analgesia efficiently decreases postoperative pain (1). Therefore, we studied in a prospective double blind study the effect of pre-operative epidural morphine associated with general anaesthesia (GA) on intra- and post-operative pain intensity.

Material and methods: 20 ASA 1 or 2 patients, scheduled for major intra-abdominal surgery were randomized in 2 groups: Group I (n = 10) received lumbar subcutaneous injection of 3 ml 2% lidocaine with 1/200,000 epinephrine; Group II (n = 10) received an epidural injection at l3-l4 interspace of 5 mg preservative free morphine in 10 ml of 0.9% saline after a test dose of 2% lidocaine (3 ml) with 1/200,000 epinephrine. Thereafter, both group received GA with thiopentone, pancuronium and fentanyl 2 µg/kg. GA was maintained with isoflurane 1 MAC in O2 (40%)-N2O (60%). Fentanyl (2 µ/kg) reinjections were based on the following criteria: > 15 mmHg increase in systolic blood pressure, >15% increase in heart rate in absence of hypovolemia, expression of pain (sweat, tears, flushing). Post-operative pain relief was performed using morphine by PCA device (bolus demand dose: 1mg; lockout period: 10 min; no basal infusion rate). No other opiates or sedatives were administred. Pain score on a 10 cm visual analog scale (VAS) was recorded every 4 hours during 3 days. Intra- and post-operative analgesia was evaluated by means of: total amount of fentanyl used during anaesthesia, time between end of surgery and first demand of analgesia, total amount of iv morphine used during 3 days by periods of 12 hours, maximum score of VAS during the same periods. Side effects were noted.

Results and discussion: Demographic data and duration of surgery were similar in both groups. Intra-operative use of fentanyl, post-operative needs of morphine for the 3 days and at 12 h, 24h and 72h were significantly lower in group II. Also, the pain score was significantly lower 24 h, 36 h, 60 h and 3 days after surgery. Delays between end of surgery were numerically higher in group II (see Table and figures). No serious complication was noted.

Conclusion: Single injection of 5 mg epidural morphine before major surgery has provided intra- and post-operative pain relief. During 3 days, patients needed very little amount of morphine almost during the first 12 hours allowing a soft recovery. Moreover, analgesia was more effective during 3 days.

	Fentanyl (mcg)	Total morphine (mg)	12 h morphine (mg)	Delay of first inj (min)
Group I	983 ± 682	85.7 ± 42.2	21.4 ± 13.8	232 ± 259
Group II	465 ±179*	36.9 ± 24.5**	3.1 ± 3.07**	480 ± 387

A.204

ADDITION OF DROPERIDOL TO PCA MORPHINE: WHAT IS THE OPTIMAL DOSE?

C.T. Lamond, D.L. Robinson, J. T. Boyd,
J. N. Cashman

Department of Anaesthetics, St. Georges Hospital,
London, U.K.

Background and study aim: Patient Controlled Analgesia (PCA) is an increasingly popular method of providing effective and safe postoperative pain relief. However, there is a high incidence of nausea and vomiting (N&V) associated with iv PCA opioid administration, especially after gynaecological surgery. Although im promethazine (1) and transdermal hyoscine (2) can reduce the severity of N&V, the incidence remains unacceptably high. In contrast low dose iv droperidol (20 mcg/kg) is an effective antiemetic with few side effects. We have noted that N&V associated with iv opioid infusions, either continuous or PCA, can be reduced by the addition of droperidol to the infusate. This study was designed to find the optimal dose of droperidol to add to the PCA morphine infusate without increasing side effects.
Patients and methods: Ethics committee approval was obtained for a double blind, randomised, controlled study of healthy female patients (aged 18-65 yr) undergoing elective gynaecological surgery under general anaesthesia. Patients who had received preoperative opioid or antiemetic therapy were excluded. A standardised anaesthetic technique was used; premedication with temazepam 10-30 mg, induction with thiopentone 3-5 mg/kg and vecuronium 0.1 mg/kg followed by morphine 0.1-0.2mg/kg and isoflurane (<2%) in nitrous oxide and oxygen. Patients were randomised into one of 4 groups to receive morphine 1mg/ml plus droperidol either 0.05, 0.1, 0.15 or 0.2 mcg/ml via a Bard PCA pump delivering 1 ml bolus with a 5 min lockout period. Patients were allowed rescue medication of im metoclopramide 10 mg. PCA was commenced in recovery, with patients assessed every 15 min for the first hour, hourly for 4 hours and 4 hourly thereafter. N&V, sedation and pain were assessed using 5 point verbal rating scales. At the end of the 48 hour study period requirement for rescue antiemetic, occurence of neuroleptic side effects and patient satisfaction with therapy were recorded.
Results and discussion: In a pilot study droperidol 0.1 mcg/ml added to the PCA morphine infusate reduced the incidence of N&V from >60% to <10%. The effect of varying the dose of droperidol added to the PCA morphine infusate on N&V, sedation and the incidence of neuroleptic side effects will be presented.
Conclusion: Droperidol is an effective antiemetic when used with PCA morphine but at the expense of increasing sedation as dose increases.

EFFECTS OF EPIDURAL CLONIDINE ON ANAESTHETIC REQUIREMENTS AND POSTOPERATIVE ANALGESIA

E. Samsó, G. Murga*, J. Valles, LL. Gallart, MM. Puig

Depts. of Anaesthesiology Hospital del Mar and Hospital de Figueres*, Autonomous University of Barcelona, Spain

Alpha$_2$ adrenergic agonists decrease intra and post-op analgesic requirements when administered transdermal, p.o., i.v.or i.m. The aim of the present study was to determine the effects of a single dose of epidural clonidine on anaesthetic requirements and post-op analgesia during epi-general anaesthesia.
Methods. Sixty ASA I-II patients scheduled for total abdominal hysterectomy were randomly distributed into groups:

GROUP	GEN ANAESTH(GA)+ EPIDURAL(EP)		
I	ISOFLURANE(IS)	+	SALINE(SS)
II	ISOFLURANE	+	CLONIDINE(CL)
III	FENTANYL(FE)	+	SALINE
IV	FENTANYL	+	CLONIDINE

Institutional and individual informed consents were obtained. After placement of an EP catheter, GA was induced with atropine, midazolam, thiopental and vecuronium. At this time, all patients received 15 ml of EP SS with or without clonidine (300 ug). Surgical anaesthesia was maintained with 60% N2O in O2, plus IS or FE administered at the doses required to keep BP and HR within 20% of baseline values. Groups III and IV also had a constant infusion of midazolam (0.75 ug/kg/min). Results are expressed as % expired IS (weighted mean of the overall concentrations obtained by mass spectrometry), and mean dose of FE in ug/kg/h.
Results: All groups were similar in respect to age, BMI, MAP, HR and duration of surgery. Anaesthetic requirements and time of request of post-op analgesia (AR) are shown in the Table.

GROUP	% IS	FE(ug/kg/h)	AR(min)
I	0.51±0.03	—	57±6
II	0.17±0.02**	—	130±18**
III	—	3.4±0.4	72±31
IV	—	2.0±0.1*	235±33**

mean ± SEM; *$p<0.05$ and **$p<0.01$

Conclusions. EP clonidine: a) decreases intra-operative FE and IS requirements and b) increases AR time, demonstrating significant post-operative analgesia.

A.206

SAFETY OF PCA IN ELDERLY

E.Santangelo*, B.Amantea*, A.Sansone,
G.Savoia, B.Sparacia

Department of Anaesthesia and Intensive Care
Catanzaro* and Palermo Medical Schools, Italy.

Background and goal of study: The goal of our study was to demonstrate the safety of PCA in patients older than 65 years, in order to verify absence of major desaturations or great alterations of respiratory patterns. We have compared ketorolac, morphine and buprenorphine PCA in 3 groups of 20 elderly.

Materials and methods: 60 patients older than 65 years submitted to median laparotomy, anaesthetized with standard balanced tecnique (propofol 1,5-2 mg/kg, isoflurane 1,3 MAC, fentanyl 1,5-3 mcg/kg, atracurium 500mcg/kg) were treated with PCA in the first 24 postoperative hours. PCA details are showed in tab.I.

Tab.I: PCA details

	Group A(20) ketorolac mg	Group B(20) morphine mg	Group C(20) buprenor.mcg
initial bolus	9	3	90
bolus dose	3	1	30
continuous infusion hourly	1,5	0,5	15
max 24h	180	60	1000
lockout time	15'	15'	15'

We have evaluated 24 hours consumption, VAS integrated score(Σ of hourly VAS 0-10 cm- 0-240 values), the number of patients with pain relief of 50% in the first 4 hours, number of patients with sedation score (0-4 points)>2, number of patients >3 major desaturations (SaO2%<85%, >30''), incidence of nausea and vomiting and minimental status evaluation at 24 hours.

Results and discussion: As showed in tab.II, collateral effects are minimal and easily controllable; better quality of analgesia was achieved with buprenorphine; safety, but not better analgesia was found using ketorolac.

Tab.II: Results

	Group A ketorolac mg	Group B morphine mg	Group C bupreno.mcg
24h consumption	75(57-127)	18(12-26)	550(400-700)
VAS integrated score	80(42-123)	72(36-110)	65(30-106)
n° of pt with 1/2 VAS in the first 24h	7/20	10/20	14/20
sedation score > 2	0/20	3/20	4/20
n° of pt with plus than 3 major desaturation	0/20	4/20	3/20
nausea/vomiting	7/5	8/6	6/5
24h minimental status range	20-24	16-22	18-23

Conclusion: Postoperative pain control with PCA in elderly is safe, even if further studies are necessary to improve quality of analgesia and to find better drugs associations.

A.207

POSTOPERATIVE HYPOXAEMIA : COMPARISON OF EPIDURAL AND PATIENT CONTROLLED ANALGESIA

Amanda Spencer, Fayezi Farhat, Jean-Louis Bourgain,
Christian Jayr

Department of anesthesiology, Institut Gustave Roussy,
Villejuif, France

Background and goal of study : It has been previously demonstrated that postoperative extradural opioid analgesia tended to cause longer periods of postoperative hypoxaemia than parenteral opioid analgesia (1). The aim of this study was to examine the effect on postoperative arterial oxygenation hemoglobin saturation (SaO2) of two different analgesia regimens ; epidural and patient controlled-analgesia after abdominal surgery for cancer.

Materials and methods : Twenty patients scheduled for abdominal surgery for cancer gave informed consent to this study. The group EPI received postoperatively epidural bupivacaine 0.125% (50 mg/4h) and morphine (1 mg/4h) - The group PCA received postoperatively self adminestered IV morphine at a maximum rate of 1 mg every 5 min using patient controlled- analgesia system. All patients received etomidate, fentanyl, vecuronium, isoflurane and O2/N2O general anesthesia. Arterial oxygen saturation was monitored continuously during the preoperative night and for 24 hours after operation, while the patient breathed air, using a Nellcor N-200 pulse oximeter interfaced with a microcomputer. Recordings of SaO2 were made every 10 seconds and stored by the computer. The percentage of time spent with SaO2 between 95% and 90%, 90% and 85% and less than 85% was analysed for the two groups and individual patients. Pain scores were obtained after operation using a 0-10 cm visual analogue scale. For statistical analysis between groups, analysis of variance with repeated measures was used.

Results : Patients in the EPI and PCA groups were not statistically different with respect to age, sex, preop SaO2. In the EPI group the pain relief was significantly better. Results of SaO2 are in the table.

Conclusion : Postoperative hypoxaemia occured in both analgesia groups but no statistical difference was found between the two groups. Epidural morphine associated with local anesthetic did not tend to cause longer episods of postoperative hypoxaemia compared with these of patient-controlled morphine analgesia group.

SaO2	EPI Group n = 10	PCA Group n = 10
Pre-op.		
<95%	20 (15)	25 (16)
Postop.		
<95%	48 (15)	55 (16)
<90%	20 (10)	15 (8)
<85%	2 (4)	2 (3)

Duration of hypoxaemia (percentage of time). Values are means (SD).

PHARMACOKINETICS OF INTRANASAL FENTANYL

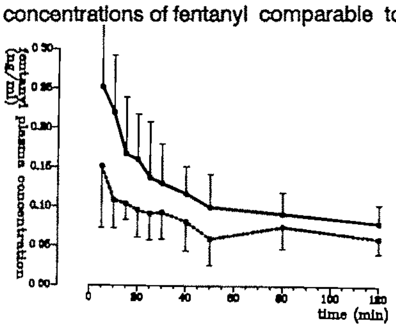
*Striebel H. Walter, **Krämer Joachim, ***Luhmann Ingeborg, ***Rohierse-Hohler Ingrid, *Tritsch Andreas

*Department of Anaesthesiology and Intensive Care Medicine, Steglitz Medical Center, Free University of Berlin, FRG
**Department of Anaesthesiology, Urban Hospital, Berlin, FRG
***Janssen Research Foundation, Neuss, FRG

Background and goal of study: We recently demonstrated that fentanyl titration can be adjusted to individual requirements by intranasal administration (1). To date there exists no pharmacokinetic data about intranasal fentanyl.

Materials and methods: The study was approved by the local ethics committee. In a randomized, double-blind cross-over study, 8 volunteers received either 12 premetered puffs (0.054 mg) of fentanyl intranasally and simultaneously 12 ml NaCl 0.9% intravenously, or 12 puffs of NaCl 0.9% intranasally and 12 ml of a diluted fentanyl solution (0.054 mg) intravenously. There was a time lag of at least 7 days between the two pharmacokinetic studies. Venous blood was sampled from a cubital vein at 5, 10, 15, 20, 25, 30, 40, 50, 80 and 120 min after dosing. C_{max}, t_{max}, AUC $t_0 - t_\infty$ and bioavailability were calculated.

Results and discussion: Median values: C_{max} (ng/ml) nasal: 0.16, i.v.: 0.26; t_{max} (min) nasal: 10, i.v. 5; AUC $t_0 - t_\infty$ (min · ng/ml) nasal: 14.6, i.v. 22.0; bioavailability (%) nasal: 76.6. Intranasal fentanyl (---) administration provides a rapid rise in plasma concentrations of fentanyl comparable to i.v. (——) administration (Fig.). The bioavailability of 76.6% is rather high and comparable to those of intranasal sufentanil (2).



Conclusion: Intranasal fentanyl is characterized by rapid resorption and a high bioavailability.

A.209

INTRANASAL FENTANYL FOR POSTOPERATIVE PAIN MANAGEMENT IN AN UNSELECTED POPULATION

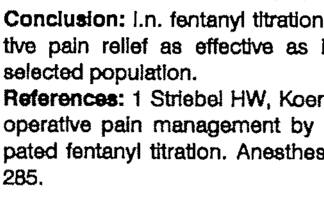
Walter H. Striebel, Jens Pommerening,
Armin Rieger, Glenda Brummer

Department of Anaesthesiology and Operative Intensive Care Medicine, Steglitz Medical Center, Free University of Berlin, FRG

Background and goal of study: In patients undergoing surgery for lumbar disc protrusion, intranasal (i.n.) fentanyl provides a pain relieving effect comparable to intravenous (i.v.) fentanyl (1). The aim of the study was to investigate whether i.n. fentanyl is suitable for postoperative pain management under routine conditions (different types of premedication, surgery and anesthesia).

Materials and methods: After approval by the local ethics committee and written consent 112 patients (ASA I,II,III) were included in this study. For postoperative pain relief patients received either 0.027 mg fentanyl i.n. and NaCl 0.9% i.v. (i.n. group, n = 53) or NaCl 0.9% i.n. and 0.027 mg fentanyl i.v. (i.v. group, n = 59). These doses were repeated every 5 min. until the patients were free of pain or refused further analgesia. Subjective pain intensity was evaluated with a numerical rating scale (0 = no pain; 100 = worst pain possible) before beginning opioid titration and 5, 10, 15, 20, 30, 40, 50, 60, 70 and 80 min. thereafter.

Results and discussion: The two groups were not statistically different with respect to age, weight, height, duration of surgery and anesthesia. The patients in the i.v. group required 0.099 ± 0.06 mg fentanyl versus 0.106 ± 0.06 mg in the i.n. group (n.s.). Subjective pain intensity decreased significantly within 5 min. in the i.v. (——) as well as in the i.n. (---) group (Wilcoxon-test for matched pairs) (Fig.; median and interquartile range). Only at the 15-min. measurement point was pain intensity significantly lower in the i.v. group (Mann-Whitney U-test). No patient required naloxone.



Conclusion: I.n. fentanyl titration provides a postoperative pain relief as effective as i.v. fentanyl in an unselected population.

A.210

INTRANASAL FENTANYL FOR BREAKTHROUGH CANCER PAIN OR INCIDENT PAIN

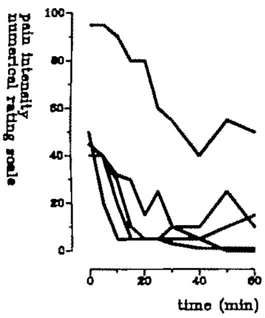
Walter H. Striebel, Anne Wessel, Armin Rieger,
Natalie Boerger

Department of Anaesthesiology and Operative Intensive
Care Medicine, Steglitz Medical Center,
Free University of Berlin, FRG

Background and goal of study: A high percentage of patients with chronic malignant pain transitory experience breakthrough cancer pain or incident pain. For "rescue" medication a fast acting and powerful analgesic should be available to the patient (1). Recent studies have shown, that intranasal (i.n.) fentanyl meet these criteria (2).

Materials and methods: The aim of this pilot study was to investigate the suitability of demand-adapted, i.n. fentanyl administration for breakthrough cancer pain or incident pain. The study was approved by the local ethics committee. Written consent was given by 5 patients. When experiencing acute worsening of pain, i.n. fentanyl (0.027 mg) via a spray bottle with a premetered spray was administered. This fentanyl dosage was repeated in 5 minute intervals until the patients experienced marked pain relief. Subjective pain intensity was assessed with a numerical rating scale (0=no pain, 100=worst pain possible).

Results and discussion: During the study period the 5 patients received a total of 0.189 mg, 0.108 mg, 0.162 mg, 0.054, 0.216 mg of fentanyl. Rapid onset and marked reduction of pain intensity was achieved in all patients (Fig.). All patients rated the pain relief as good or very good. Pain in the nose was not reported.



Conclusion: This open study shows that i.n. fentanyl provides fast acting, efficacious and non invasive pain reduction in patients with breakthrough cancer pain or incident pain. Further studies are warranted.

A.211

TREATMENT OF CANCER PAIN WITH MORPHINE (MO) - A DOUBLE BLIND STUDY OF EXTRADURAL (ED) VERSUS INTRAMUSCULAR (im) ROUTES OF ADMINISTRATION.

Sherdil Nath and Gunnel Ehrenström Reiz.

From the Department of Anaesthesiology, University of Umeå, Umeå, Sweden.

Background and goal of study: ED administration of MO or other opioids is a well established technique for treatment of cancer pain. Despite its wide-spread use, controlled data of its efficacy in relation to the type of pain are lacking. One uncontrolled study (1) and much clinical experience do, however, indicate that ED MO has little or no effect in neurogenic pain. The aim of this study was to compare the efficacy of extradurally administered MO on terminal cancer pain using a classical double-blind, partly cross-over design with im MO as the control.

Patients and methods: Forty patients with severe, terminal cancer pain and unsatisfactory response to oral or parenteral analgesics were incuded in the study after institutional approval and informed consent. A malignant focus of pain was always identified. The type of pain was described as musculo-skeletal (MS), visceral (V), neurogenic (N) or any combination thereof. Patients were randomized to receive either ED MO, 4 mg in 10 ml normal saline (NS) given 6 hourly along with an im injection of 1 ml NS, or 10 mg (1ml) MO im along with 10 ml of ED NS at the same intervals. The double-blind regimen was maintained for 72 h and visual analogue scores (0-10) obtained 1 hour after each dose. Additional analgesics (pethidine or ketobemidone) were given im as needed. After 72 h, patients who had received im MO were switched to ED MO, individually dosed, for another 72 h and patients given ED MO had their dose adjusted if required.

Results and discussion: The im group comprised 20 patients with 11 components of N, 7 of MS and 6 of V pain. Therapy was regarded as satisfactory in 2 N, 1 MS and 1 V pain. In the ED group, comprising 20 patients with 8 N, 11 MS and 4 V pains, therapy was satisfactory in 7 MS ($p<0.05$ compared to im MO), 2 V and 0 N pains. Less suplementary analgesics were required in the ED group. Of the poor responders in the im group, 2 MS and 2 V, but none of the N pains responded satisfactorily when given ED MO in an open, individually dosed fashion. When the ED MO patients had their dose adjusted after termination of the double-blind period, MS and V but not N pains could be well controlled. It is concluded that ED MO is more effective than im MO in the treatment of musculo-skeletal cancer pain but that neither of these are effective in neurogenic pain. Visceral pain can sometimes be controlled with ED MO at higher doses.

A.212

HIGH DOSE ORAL MORPHINE IN CANCER PAIN MANAGEMENT

Lukas Radbruch, Stefan Grond, Detlev Zech, Klaus A. Lehmann

Department of Anaesthesiology, University of Cologne, Cologne, Germany

Background and goal of study: Due to differences in pain type, tumor spread and individual bioavailability efficient doses of oral morphine have a wide range. Though its use in cancer pain has been thoroughly investigated, little has been published on the high dose range. In this retrospective study, efficacy and side effects of high dose oral morphine were evaluated.

Materials and methods: From 1983-1991, 705 patients (males 379, females 326, 58±12 years) with advanced cancer were treated in our pain clinic with oral morphine (solution or sustained-release tablets). 111 of these patients received 200-599 mg/d, and 14 patients 600-2400 mg/d. Pain intensity (verbal rating scale) and side effects were assessed regularly.

Results and discussion: Patients were treated on 36823 days with oral morphine. According to WHO-guidelines morphine was combined with nonopioid analgesics on 96% of treatment days and with adjuvant drugs (laxatives 68%, antiemetics 46%, hypnotics 45%, antipsychotics 21%, antidepressants 21%, anticonvulsants 20%, steroids 17%) on 97% of days. No serious adverse events, such as respiratory depression or allergic reaction, were observed.

Table: Pain intensity and symptoms during treatment with oral morphine

morphine (mg/d)	<200	200-599	≥600
days (n)	30626	5198	999
Pain intensity			
none-moderate	86%	78%	67%
severe-maximal	10%	13%	33%
no assessment	4%	9%	0%
Symptoms			
Dyspnoea	15%	7%	41%
Dysphagia	17%	18%	36%
Constipation	26%	32%	31%
Nausea	26%	23%	23%
Insomnia	23%	25%	22%
Neurol.-psych. symp.	25%	28%	21%
Anorexia	26%	28%	18%
Hyperhidrosis	13%	14%	12%
Dyspepsia	7%	7%	10%
Urinary symptoms	16%	20%	6%
Diarrhea	8%	3%	4%
Vomiting	16%	15%	3%
Pruritus	8%	6%	0%

Conclusion: Oral morphine is a safe analgesic drug even in the high dose range. Severe pain, dysphagia and dyspnoea were seen more frequently in patients with morphine doses ≥600 mg/d, representing far advanced cancer disease in these patients. Side effects of morphine therapy were not increased in this group, due to symptomatic treatment with adjuvant drugs.

A.213

INTRATHECAL PAIN RELIEF IN TERMINALLY ILL CANCER PATIENTS AT HOME.

Wagemans MFM, Zuurmond WWA, Spoelder EM, Lange JJ de.

Department of Anesthesiology, Academic Hospital Vrije Universiteit, PO BOX 7057, Amsterdam.

Forty patients with cancer pain in the terminal phase, who had either insufficient pain relief with high doses of morphine or severe side effects from systemic analgesics were selected for continuous administration of morphine. An intrathecal catheter was implanted, tunnelled and connected with a portable infusion pump, delivering morphine constantly and if needed on demand. The proper dose was titrated and after stabilization, patients were discharged from the hospital if adequate home care could be guaranteed. During hospitalization and at home, daily doses of morphine, concomitant medication, pain scores measured with help of the Visual Analogue Scale (VAS) and activities were meticulously registered in patient's pain diary. The total number of catheter days was 1486, of which 1009 were spent at home. Patients were treated for a mean of 37.2 (range 2 - 183) days.

Sufficient pain relief (a VAS score < 5) was achieved in 37 patients (92.5 %). Meningitis occurred in 2 patients, however the early detection of this complication resulted in adequate treatment with antibiotics. The catheter could be re-instilled within 10 days. Minor complications like postspinal headache and withdrawal symptoms, occurred mostly during the stabilization phase. The catheter was removed inadvertently 6 times and could be replaced on outpatient basis. In terminally ill cancer patients, the continuous intrathecal , administration of morphine may be recommended if conventional pain relief fails.

SUBJECT INDEX

Acid–base equilibrium, Changes in blood lactate, total body oxygen delivery and consumption during liver transplantation, Carrera, J., *et al.*, (*ESA*) A.77

Acid–base equilibrium, pH, Measurement of sigmoid intramural pH during orthotopic liver transplantation, Auroy, Y., *et al.*, (*ESA*) A.76

Adductor pollicis, Can repetition of high frequencies stimuli alter the value of 50 and 100 Hz tetanic fade during vecuronium induced neuromuscular blockade? Baurain, M. J., *et al.*, (*ESA*) A.135

——, Concentration–effect relationship at the vocal cords and the adductor pollicis following rocuronium administration, Plaud, B., *et al.*, (*ESA*) A.141

——, Monitoring the onset of neuromuscular blockade at the orbicularis oculi can predict good intubating conditions when using $2 \times ED_{95}$ of atracurium, Debaene, B., *et al.*, (*ESA*) A.142

Age factors, An investigation into the effect of passive and active cutaneous warming devices on intraoperative body temperature in elderly patients, Bennet, J., *et al.*, (*ESA*) A.73

——, Anesthesia for patients ⩾ 90 years of age in emergency hip surgery, Eleftheriadis, S., *et al.*, (*ESA*) A.3

——, Effectiveness of core warming on net transfer of body heat across the skin, Kulkarni, P., *et al.*, (*ESA*) A.70

——, Incidence of post dural puncture headache in young adults by the use of the Sprôtte needle: 300 patients, Descraques, C., *et al.*, (*ESA*) A.127

——, Ketamine does not prevent hypotension caused by induction of anaesthesia with propofol in elderly patients, Blockmans, D., *et al.*, (*ESA*) A.40

——, Safety of PCA in elderly, Santangelo, E., *et al.*, (*ESA*) A.206

——, The pharmacokinetics of rocuronium in pediatric patients: a pooled data analysis, Meistelman, C., *et al.*, (*ESA*) A.138

Airway, anatomy, A new clinical score to predict difficult intubation, Arné, J., *et al.*, (*ESA*) A.1

Airway, infections, A new clinical score to predict difficult intubation, Arné, J., *et al.*, (*ESA*) A.1

Airway, patency, Continuous spirometry: an aid in the intraoperative respiratory monitoring—case reports, Bardoczky, G., *et al.*, (*ESA*) A.55

Alcohol, withdrawal, Carbohydrate deficient transferrin: a new copredictor of alcoholism related postoperative complications? Heil, T., *et al.*, (*ESA*) A.88

Anaesthesia, audit, Adequate pain relief with epidural analgesia during labor: why are women still dissatisified? Hamza, J., *et al.*, (*ESA*) A.171

——, An audit of the incidence and costs associated with post operative nausea and vomiting (PONV) following major gynaecological surgery in an inpatient population, Morris, R. W., *et al.*, (*ESA*) A.2

Anaesthesia, day-case, Propofol for tracheal intubation in paediatric outpatient anaesthesia, Montasser, A. M., (*ESA*) A.161

Anaesthesia, general, Hypoxic events after general anaesthesia in the recovery room, Degasperi, D., *et al.*, (*ESA*) A.59

——, Recruitment of atelectasis during general anaesthesia: a CT-study, Rothen, H. U., *et al.*, (*ESA*) A.53

Anaesthesia, geriatric, Anesthesia for patients ⩾ 90 years of age in emergency hip surgery, Eleftheriadis, S., *et al.*, (*ESA*) A.3

——, Fentanyl or buprenorphine side effects in spinal anaesthesia, Foppoli, R, *et al.*, (*ESA*) A.132

——, Ketamine does not prevent hypotension caused by induction of anaesthesia with propofol in elderly patients, Blockmans, D., *et al.*, (*ESA*) A.40

——, Subarachnoid anaesthesia (SAA) and postoperative analgesia with bupivacaine (BV) plus fentanyl (FN) in geriatric patients, Fernandez, D., *et al.*, (*ESA*) A.131

Anaesthesia, neurosurgical, Effect of esmolol *versus* lidocaine on intracranial pressure and haemodynamic responses to laryngoscopy and intubation, Samaha, T., *et al.*, (*ESA*) A.118

Anaesthesia, obstetric, Best Quincke point needle for Caesarean section, Lyons, G., (*ESA*) A.174

——, Headache—new needles and spinal anaesthesia for C. section, Thormann, F., *et al.*, (*ESA*) A.173

——, Mechanisms of ECG changes during caesarean section (CS)—a hypothesis, Svanström, M., *et al.*, (*ESA*) A.177

——, Spinal anesthesia for C section: addition of phenylephrine to ephedrine for prevention of maternal hypotension, Thirion, A.-V., *et al.*, (*ESA*) A.172

Anaesthesia, paediatric, Blended anaesthesia in pediatric major surgery: top-up *vs* epidural continuous infusion, Savoia, G., *et al.*, (*ESA*) A.159

——, Clonidine in paediatric caudal anaesthesia, Jamali, S., *et al.*, (*ESA*) A.160

——, Continuous monitoring of Sp_{O_2} during total intravenous anaesthesia with ketamine and spontaneous ventilation, Joly, L.-M., *et al.*, (*ESA*) A.58

——, Propofol for tracheal intubation in paediatric outpatient anaesthesia, Montasser, A. M., (*ESA*) A.161

——, Relationship between arterial $P\text{CO}_2$ (Pa_{CO_2}) and end tidal CO_2 (ETco_2) recorded through a laryngeal mask (LMA) in children breathing spontaneously, Van Obbergh, L. J., *et al.*, (*ESA*) A.164

——, Ventilation with halothane is less affected in children with laryngeal mask airway than with endotracheal tube, Reignier, J., *et al.*, (*ESA*) A.162

Anaesthetic–analgesic regimens, Addition of droperidol to PCA morphine: what is the optimal dose? Lamond, C. T., *et al.*, (*ESA*) A.204

——, Blended anaesthesia in pediatric major surgery: top-up *vs* epidural continuous infusion, Savoia, G., *et al.*, (*ESA*) A.159

——, Diamorphine/bupivacaine mixture *vs* plain bupivacaine: a comparison of epidural infusions in labour, Bailey, C. R., *et al.*, (*ESA*) A.169

——, Fentanyl or buprenorphine side effects in spinal anaesthesia, Foppoli, R, *et al.*, (*ESA*) A.132

——, Postoperative hypoxaemia: comparison of epidural and patient controlled analgesia, Spencer, A., *et al.*, (*ESA*) A.207

——, Propofol anaesthesia with spontaneous breathing for extracorporeal shock wave lithotripsy, Pasch, T., *et al.*, (*ESA*) A.153

——, Subarachnoid anaesthesia (SAA) and postoperative analgesia with bupivacaine (BV) plus fentanyl (FN) in geriatric patients, Fernandez, D., *et al.*, (*ESA*) A.131

Anaesthetic techniques, bronchoscopy, Fiberoptic bronchoscopy in brain dead organ donors, Riou, B., *et al.*, (*ESA*) A.80

Anaesthetic techniques, extradural, Blended anaesthesia in pediatric major surgery: top-up *vs* epidural continuous infusion, Savoia, G., *et al.*, (*ESA*) A.159

——, Does exogenous dopamine reverse cardiovascular depression induced by isoflurane during thoracic epidural blockade? Raner, C., *et al.*, (*ESA*) A.49

——, Effects of epidural clonidine on anaesthetic requirements and postoperative analgesia, Samsó, E., *et al.*, (*ESA*) A.205

——, Epidural blood patch for treatment of postdural puncture headache, Rosenberg, P. H., *et al.*, (*ESA*) A.129

——, Influence of cervicothoracic epidural anaesthesia (C-TEA) on left ventricular (LV) contractility—an experimental study in pigs with autonomous blockade, Reiz, S., *et al.*, (*ESA*) A.52

——, Sequential spinal peridural anaesthesia for gynaecological surgery under laparoscopy, Joos, S., *et al.*, (*ESA*) A.130

——, The effect of parenteral diclofenac and morphine on efficacy duration and height of blockade during continuous epidural bupivacaine 0.5%, Forbes, D., *et al.*, (*ESA*) A.125

——, The effects of epidural and spinal anesthesia on the changes in the plethysmographic signal in the lower and upper limbs, Preisman, S., *et al.*, (*ESA*) A.124

Anaesthetic techniques, fibreoptic, Direct, indirect or flexible laryngoscopy after thyroidectomy? Lacoste, L., *et al.*, (*ESA*) A.66

Anaesthetic techniques, hypotensive, Does nicardipine potentiate the neuromuscular block of atracurium? Bazin, J. E., *et al.*, (*ESA*) A.136

Anaesthetic techniques, hypothermia, Core–peripheral temperature difference in early *vs* later extubation after coronary artery surgery, Knapik, P., *et al.*, (*ESA*) A.69

Anaesthetic techniques, i.m., Slow-release effect of pH-adjusted bupivacaine: pharmacokinetic demonstration, Benhamou, D., *et al.*, (*ESA*) A.120

Anaesthetic techniques, induction, Determination of a pharmacokinetic model for propofol induction of anaesthesia, Viviand, X., *et al.*, (*ESA*) A.150

——, Quality of Induction: a clinical comparison of Etomidat-Lipuro® and Hypnomidate®, Wiebalck, A., *et al.*, (*ESA*) A.154

Anaesthetic techniques, inhalation, Influence of anaesthesia on post-operative hypoxaemia, Georgiou, L., *et al.*, (*ESA*) A.60

——, Is correlation of arterial and end-tidal carbon dioxide pressure during inhalation anaesthesia better with laryngeal mask as compared to face mask? Ivens, D., *et al.*, (*ESA*) A.17

——, Ventilation with halothane is less affected in children with laryngeal mask airway than with endotracheal tube, Reignier, J., *et al.*, (*ESA*) A.162

Anaesthetic techniques, insufflation, Abdominal wall retraction may decrease anaesthesiological risks of laparoscopic cholecystectomy, Vereczkey, Z., *et al.*, (*ESA*) A.64

——, Influence of pneumoperitoneum and posture on hemodynamic and stress responses during anaesthesia for laparoscopic surgery, Odeberg, S., *et al.*, (*ESA*) A.34

——, Neuroendocrine changes during pneumoperitoneum for laparoscopic cholecystectomy, Joris, J., *et al.*, (*ESA*) A.33

——, Respiratory effects of laparoscopic cholecystectomy (preliminary data), Crea, M. A., *et al.*, (*ESA*) A.63

Anaesthetic techniques, i.v., Continuous monitoring of Sp_{O_2} during total intravenous anaesthesia with ketamine and spontaneous ventilation, Joly, L.-M., *et al.*, (*ESA*) A.58

——, Influence of anaesthesia on post-operative hypoxaemia, Georgiou, L., *et al.*, (*ESA*) A.60

——, Total intravenous anaesthesia (TIVA) with propofol and alfentanil for renal transplantation, Kirvelä, M., *et al.*, (*ESA*) A.81

Anaesthetic techniques, i.v. infusion, Computer-controlled syringe pump improves safety of pharmacokinetic models, Duranteau, R., *et al.*, (*ESA*) A.148

——, Determination of a pharmacokinetic model for propofol induction of anaesthesia, Viviand, X., *et al.*, (*ESA*) A.150

——, Pharmacokinetics of propofol and its conjugates after continuous infusion in normal and renal failure patients, Nathan, N., *et al.*, (*ESA*) A.151

——, Prolonged (> 1 week) sedation with midazolam in ICU patients: efficacy, safety and pharmacokinetics, Heytens, L., *et al.*, (*ESA*) A.178

——, Propofol anaesthesia with spontaneous breathing for extracorporeal shock wave lithotripsy, Pasch, T., *et al.*, (*ESA*) A.153

Anaesthetic techniques, laryngoscopy, Day 0 or day 3 laryngoscopy after thyroidectomy? Lacoste, L., *et al.*, (*ESA*) A.67

——, Direct, indirect or flexible laryngoscopy after thyroidectomy? Lacoste, L., *et al.*, (*ESA*) A.66

Anaesthetic techniques, regional, brachial plexus, Motor blockade and absence of local nerve toxicity induced by liposomal bupivacaine injected into the axillary brachial plexus of rabbits, Legros, F. J., *et al.*, (*ESA*) A.122

Anaesthetic techniques, regional, caudal, Clonidine in paediatric caudal anaesthesia, Jamali, S., *et al.*, (*ESA*) A.160

Anaesthetic techniques, subarachnoid, Best Quincke point needle for Caesarean section, Lyons, G., (*ESA*) A.174

——, Effects of intrathecal meperidine (MP), fentanyl (FN) and lidocaine (LD) on somatosensory (SSEP) and cortical motor (CMEP) evoked potentials in humans, Fernandez, S., *et al.*, (*ESA*) A.119

——, Fentanyl or buprenorphine side effects in spinal anaesthesia, Foppoli, R, *et al.*, (*ESA*) A.132

——, Headache—new needles and spinal anaesthesia for C. section, Thormann, F., *et al.*, (*ESA*) A.173

——, Incidence of post dural puncture headache in young adults by the use of the Sprôtte needle: 300 patients, Descraques, C., *et al.*, (*ESA*) A.127

——, Nine years of clinical experience with 29 gauge spinal needles, Dittmann, M., *et al.*, (*ESA*) A.126

——, Postdural puncture headaches are not related to the duration of spinal catheter placement, Liu, N., *et al.*, (*ESA*) A.128

——, Sequential spinal peridural anaesthesia for gynaecological surgery under laparoscopy, Joos, S., *et al.*, (*ESA*) A.130

——, Spinal anesthesia for C section: addition of phenylephrine to ephedrine for prevention of maternal hypotension, Thirion, A.-V., *et al.*, (*ESA*) A.172

——, Subarachnoid anaesthesia (SAA) and postoperative analgesia with bupivacaine (BV) plus fentanyl (FN) in geriatric patients, Fernandez, D., *et al.*, (*ESA*) A.131

——, The effects of epidural and spinal anesthesia on the changes in the plethysmographic signal in the lower and upper limbs, Preisman, S., *et al.*, (*ESA*) A.124

Anaesthetic techniques, topical, Laryngeal function as assessed by tussometry following topical anaesthesia, Mahajan, R. P., *et al.*, (*ESA*) A.68

Anaesthetics gases, nitrous oxide, Effects of nitrous oxide (N_2O) on systemic haemodynamics, regional left ventricular (LV) function and incidence of myocardial ischaemia (MI) in vascular surgical patients with coronary artery disease (CAD), Hohner, P., *et al.*, (*ESA*) A.41

——, Influence of anaesthesia on post-operative hypoxaemia, Georgiou, L., *et al.*, (*ESA*) A.60

——, Neuromuscular blockade following mivacurium in children during N_2O–halothane, Orliaguet, G., *et al.*, (*ESA*) A.163

——, Nitrous oxide induced neuronal depression: modification through benzodiazepine receptors, Dzoljic, M., *et al.*, (*ESA*) A.112

Anaesthetics i.v., droperidol, Addition of droperidol to PCA morphine: what is the optimal dose? Lamond, C. T., *et al.*, (*ESA*) A.204

——, Comparison of ondansetron, metoclopramide and droperidol for the prophylaxis of emetic symptoms after gynecological laparoscopic procedures, Geiger, C., *et al.*, (*ESA*) A.14

——, Double-blind comparison of ondansetron, droperidol and saline for prevention of nausea & vomiting after orthopaedic surgery, Gan, T. J., *et al.*, (*ESA*) A.13

——, Ondansetron 4 mg *vs* droperidol 1.25 mg in the prophylaxis of postoperative nausea and vomiting after alfentanil-supplemented inhalation anaesthesia, Alon, E., *et al.*, (*ESA*) A.12

Anaesthetics i.v., etomidate, Adrenocortical function: a clinical comparison of Etomidat-Lipuro® and Hypnomidate®, Wiebalck, A., *et al.*, (*ESA*) A.90

——, Quality of Induction: a clinical comparison of Etomidat-Lipuro® and Hypnomidate®, Wiebalck, A., *et al.*, (*ESA*) A.154

Anaesthetics i.v., ketamine, Continuous monitoring of Sp_{O_2} during total intravenous anaesthesia with ketamine and spontaneous ventilation, Joly, L.-M., *et al.*, (*ESA*) A.58

——, Ketamine does not prevent hypotension caused by induction of anaesthesia with propofol in elderly patients, Blockmans, D., *et al.*, (*ESA*) A.40

——, Midazolam prevents ketamine-induced stimulation of cerebral metabolism, Åkeson, J., *et al.*, (*ESA*) A.111

Anaesthetics i.v., propofol, Alizapride does reduce pain on injection of propofol: comparison with lidocaine, Zaouk, G., *et al.*, (*ESA*) A.11

——, Determination of a pharmacokinetic model for propofol induction of anaesthesia, Viviand, X., *et al.*, (*ESA*) A.150

——, Gastric mucosal perfusion is better preserved during cardiac surgery when isoflurane rather than enflurane or propofol is used to maintain anaesthesia, Mythen, M., *et al.*, (*ESA*) A.29

——, Influence of anaesthesia on post-operative hypoxaemia, Georgiou, L., *et al.*, (*ESA*) A.60

——, Ketamine does not prevent hypotension caused by induction of anaesthesia with propofol in elderly patients, Blockmans, D., *et al.*, (*ESA*) A.40

——, Pharmacokinetics of propofol and its conjugates after continuous infusion in normal and renal failure patients, Nathan, N., *et al.*, (*ESA*) A.151

——, Propofol (2,6 diisopropylphenol) as an antioxidant *in-vitro*: a dose response study, Bennett, S., *et al.*, (*ESA*) A.152

——, Propofol anaesthesia with spontaneous breathing for extracorporeal shock wave lithotripsy, Pasch, T., *et al.*, (*ESA*) A.153

——, Propofol for tracheal intubation in paediatric outpatient anaesthesia, Montasser, A. M., (*ESA*) A.161

——, Propofol/fentanyl-anesthesia in patients with highly depressed cardiac function, Rauch, H., *et al.*, (*ESA*) A.30

——, Target-controlled intravenous sedation with propofol, Mergaert, C., *et al.*, (*ESA*) A.149

——, Total intravenous anaesthesia (TIVA) with propofol and alfentanil for renal transplantation, Kirvelä, M., *et al.*, (*ESA*) A.81

——, Transcranial Doppler sonography: effect of propofol and

thiopental in patients with brain tumors and brain injuries, Schregel, W., *et al.*, (*ESA*) A.105
Anaesthetics i.v., thiopentone, Transcranial Doppler sonography: effect of propofol and thiopental in patients with brain tumors and brain injuries, Schregel, W., *et al.*, (*ESA*) A.105
Anaesthetics local, bupivacaine, Analgesia by wound infiltration before or after surgery in inguinal hernioraphy, Hennart, D., *et al.*, (*ESA*) A.202
——, Blended anaesthesia in pediatric major surgery: top-up *vs* epidural continuous infusion, Savoia, G., *et al.*, (*ESA*) A.159
——, Diamorphine/bupivacaine mixture *vs* plain bupivacaine: a comparison of epidural infusions in labour, Bailey, C. R., *et al.*, (*ESA*) A.169
——, Diaphragmatic function after bupivacaine cervical extradural analgesia for chronic pain therapy, Nyström, E., *et al.*, (*ESA*) A.65
——, Epidural administration of liposomal bupivacaine for the management of postsurgical pain, Boogaerts, J., *et al.*, (*ESA*) A.200
——, Fentanyl or buprenorphine side effects in spinal anaesthesia, Foppoli, R, *et al.*, (*ESA*) A.132
——, Lemakalim reverses ventricular conduction impairment induced by a large dose of bupivacaine in anesthetized dogs, de La Coussaye, J. E., *et al.*, (*ESA*) A.121
——, Motor blockade and absence of local nerve toxicity induced by liposomal bupivacaine injected into the axillary brachial plexus of rabbits, Legros, F. J., *et al.*, (*ESA*) A.122
——, Patient controlled epidural analgesia *vs* intermittent injections during labor using 0.125% bupivacaine and sufentanil, Baudot, J., *et al.*, (*ESA*) A.170
——, Postoperative hypoxaemia: comparison of epidural and patient controlled analgesia, Spencer, A., *et al.*, (*ESA*) A.207
——, Slow-release effect of pH-adjusted bupivacaine: pharmacokinetic demonstration, Benhamou, D., *et al.*, (*ESA*) A.120
——, Subarachnoid anaesthesia (SAA) and postoperative analgesia with bupivacaine (BV) plus fentanyl (FN) in geriatric patients, Fernandez, D., *et al.*, (*ESA*) A.131
——, The effect of parenteral diclofenac and morphine on efficacy duration and height of blockade during continuous epidural bupivacaine 0.5%, Forbes, D., *et al.*, (*ESA*) A.125
——, The effects of bupivacaine, mepivacaine and prilocaine on platelet aggregation, Bayhan, N., *et al.*, (*ESA*) A.123
——, Use of thoracic epidural block for perioperative analgesia in children, Entress, A. H., *et al.*, (*ESA*) A.158
Anaesthetics local, lignocaine, Alizapride does reduce pain on injection of propofol: comparison with lidocaine, Zaouk, G., *et al.*, (*ESA*) A.11
——, Effect of esmolol *versus* lidocaine on intracranial pressure and haemodynamic responses to laryngoscopy and intubation, Samaha, T., *et al.*, (*ESA*) A.118
——, Effects of intrathecal meperidine (MP), fentanyl (FN) and lidocaine (LD) on somatosensory (SSEP) and cortical motor (CMEP) evoked potentials in humans, Fernandez, S., *et al.*, (*ESA*) A.119
——, Fentanyl, as pethidine, inhibits post anaesthesia shivering, Alfonsi, P., *et al.*, (*ESA*) A.74
——, Laryngeal function as assessed by tussometry following topical anaesthesia, Mahajan, R. P., *et al.*, (*ESA*) A.68
Anaesthetics local, mepivacaine, The effects of bupivacaine, mepivacaine and prilocaine on platelet aggregation, Bayhan, N., *et al.*, (*ESA*) A.123
Anaesthetics local, prilocaine, The effects of bupivacaine, mepivacaine and prilocaine on platelet aggregation, Bayhan, N., *et al.*, (*ESA*) A.123
Anaesthetics volatile, desflurane, Local *versus* neurogenic vasodilator effects of desflurane and isoflurane in the small intestine, Sundeman, H., *et al.*, (*ESA*) A.50
Anaesthetics volatile, enflurane, Effects of oral preoperative guanfacine on anesthetics requirements, Engelman, E., *et al.*, (*ESA*) A.144
——, Gastric mucosal perfusion is better preserved during cardiac surgery when isoflurane rather than enflurane or propofol is used to maintain anaesthesia, Mythen, M., *et al.*, (*ESA*) A.29
Anaesthetics volatile, halothane, Isoproterenol reverses the MAC decreasing effect of esmolol in rats, Perel, A., *et al.*, (*ESA*) A.117
——, Neuromuscular blockade following mivacurium in children during N_2O–halothane, Orliaguet, G., *et al.*, (*ESA*) A.163
——, Ventilation with halothane is less affected in children with laryngeal mask airway than with endotracheal tube, Reignier, J., *et al.*, (*ESA*) A.162
Anaesthetics volatile, isoflurane, Does exogenous dopamine reverse cardiovascular depression induced by isoflurane during thoracic epidural blockade? Raner, C., *et al.*, (*ESA*) A.49
——, Effects of oral preoperative guanfacine on anesthetics requirements, Engelman, E., *et al.*, (*ESA*) A.144
——, Gastric mucosal perfusion is better preserved during cardiac surgery when isoflurane rather than enflurane or propofol is used to maintain anaesthesia, Mythen, M., *et al.*, (*ESA*) A.29
——, Influence of anaesthesia on post-operative hypoxaemia, Georgiou, L., *et al.*, (*ESA*) A.60
——, Isoflurane inhibits Ca^{2+}-induced insulin secretion from electrically permeabilised islets of Langerhans, Desborough, J. P., *et al.*, (*ESA*) A.91
——, Local *versus* neurogenic vasodilator effects of desflurane and isoflurane in the small intestine, Sundeman, H., *et al.*, (*ESA*) A.50
Analgesia, geriatric, Subarachnoid anaesthesia (SAA) and postoperative analgesia with bupivacaine (BV) plus fentanyl (FN) in geriatric patients, Fernandez, D., *et al.*, (*ESA*) A.131
Analgesia, obstetric, Adequate pain relief with epidural analgesia during labor: why are women still dissatisified? Hamza, J., *et al.*, (*ESA*) A.171
——, Diamorphine/bupivacaine mixture *vs* plain bupivacaine: a comparison of epidural infusions in labour, Bailey, C. R., *et al.*, (*ESA*) A.169
——, Patient controlled epidural analgesia *vs* intermittent injections during labor using 0.125% bupivacaine and sufentanil, Baudot, J., *et al.*, (*ESA*) A.170
Analgesia, paediatric, Clonidine in paediatric caudal anaesthesia, Jamali, S., *et al.*, (*ESA*) A.160
——, Use of thoracic epidural block for perioperative analgesia in children, Entress, A. H., *et al.*, (*ESA*) A.158
Analgesia, patient-controlled, Addition of droperidol to PCA morphine: what is the optimal dose? Lamond, C. T., *et al.*, (*ESA*) A.204
——, Patient controlled epidural analgesia *vs* intermittent injections during labor using 0.125% bupivacaine and sufentanil, Baudot, J., *et al.*, (*ESA*) A.170
——, Postoperative hypoxaemia: comparison of epidural and patient controlled analgesia, Spencer, A., *et al.*, (*ESA*) A.207
——, Safety of PCA in elderly, Santangelo, E., *et al.*, (*ESA*) A.206
Analgesia, postoperative, Addition of droperidol to PCA morphine: what is the optimal dose? Lamond, C. T., *et al.*, (*ESA*) A.204
——, Clonidine in paediatric caudal anaesthesia, Jamali, S., *et al.*, (*ESA*) A.160
——, Effect of morphine on a nociceptive flexion reflex in patients with postoperative pain, Chauvin, M., *et al.*, (*ESA*) A.115
——, Effects of epidural clonidine on anaesthetic requirements and postoperative analgesia, Samsó, E., *et al.*, (*ESA*) A.205
——, Epidural administration of liposomal bupivacaine for the management of postsurgical pain, Boogaerts, J., *et al.*, (*ESA*) A.200

——, Treatment of cancer pain with morphine (MO)—A double blind study of extradural (ED) *versus* intramuscular (im) routes of administration, Nath, S., *et al.*, (*ESA*) A.211
Analgesics opioid, pethidine, Effects of intrathecal meperidine (MP), fentanyl (FN) and lidocaine (LD) on somatosensory (SSEP) and cortical motor (CMEP) evoked potentials in humans, Fernandez, S., *et al.*, (*ESA*) A.119
——, Fentanyl, as pethidine, inhibits post anaesthesia shivering, Alfonsi, P., *et al.*, (*ESA*) A.74
——, Propofol anaesthesia with spontaneous breathing for extracorporeal shock wave lithotripsy, Pasch, T., *et al.*, (*ESA*) A.153
Analgesics opioid, sufentanil, Echocardiographic study of the induction with a low-dose of sufentanil for coronary artery surgery, Bromberg, N., *et al.*, (*ESA*) A.28
——, Patient controlled epidural analgesia *vs* intermittent injections during labor using 0.125% bupivacaine and sufentanil, Baudot, J., *et al.*, (*ESA*) A.170
——, Sufentanil first-pass pulmonary uptake at three different steady state concentrations of the drug, Boer, F., *et al.*, (*ESA*) A.147
——, Sufentanil increases intracranial pressure in patients with head trauma, Albanese, J., *et al.*, (*ESA*) A.107
Antacids, metoclopramide, Comparison of ondansetron, metoclopramide and droperidol for the prophylaxis of emetic symptoms after gynecological laparoscopic procedures, Geiger, C., *et al.*, (*ESA*) A.14
Antagonists benzodiazepine, flumazenil, Flumazenil facilitates intraoperative arousal in scoliosis surgery, Koscielniak-Nielsen, Z. J., *et al.*, (*ESA*) A.157
Antagonists benzodiazepine, Ro 15-4513, Nitrous oxide induced neuronal depression: modification through benzodiazepine receptors, Dzoljic, M., *et al.*, (*ESA*) A.112
Antagonists miscellaneous, Comparison of ondansetron, metoclopramide and droperidol for the prophylaxis of emetic symptoms after gynecological laparoscopic procedures, Geiger, C., *et al.*, (*ESA*) A.14
——, Double-blind comparison of ondansetron, droperidol and saline for prevention of nausea & vomiting after orthopaedic surgery, Gan, T. J., *et al.*, (*ESA*) A.13
——, Ondansetron 4 mg *vs* droperidol 1.25 mg in the prophylaxis of postoperative nausea and vomiting after alfentanil-supplemented inhalation anaesthesia, Alon, E., *et al.*, (*ESA*) A.12

Antagonists neuromuscular block, neostigmine, Neostigmine antagonism of neuromuscular blockade induced by mivacurium, vecuronium and atracurium, Dernovoi, B. S., *et al.*, (*ESA*) A.137

——, Reversal of vecuronium induced neuromuscular blockade: No effects of atropine administration timing, Baurain, M. J., *et al.*, (*ESA*) A.134

Antagonists opioid, miscellaneous, Differential effects of specific delta and kappa opioid antagonists on the bidirectionnal effect of naloxone in arthritic rats, Cattaneo, I., *et al.*, (*ESA*) A.114

——, Involvement of μ, δ, and κ receptors in the inhibition by intrathecal morphine of a C-fibre evoked reflex in the rat, Guirimand, F., *et al.*, (*ESA*) A.116

Antagonists opioid, naloxone, Differential effects of specific delta and kappa opioid antagonists on the bidirectionnal effect of naloxone in arthritic rats, Cattaneo, I., *et al.*, (*ESA*) A.114

Antibiotics, External ventricular CSF drains infections, Mahé, V., *et al.*, (*ESA*) A.109

Arterial pressure, drug effects, Mechanisms of ECG changes during caesarean section (CS)—a hypothesis, Svanström, M., *et al.*, (*ESA*) A.177

Arterial pressure, measurement, Clinical evaluation of the calibration of noninvasive continuous blood pressure measurement devices by means of oscillometric blood pressure measurements, de Jong, J. R., *et al.*, (*ESA*) A.15

Blood, anaesthetic concentration, Determination of a pharmacokinetic model for propofol induction of anaesthesia, Viviand, X., *et al.*, (*ESA*) A.150

——, Target-controlled intravenous sedation with propofol, Mergaert, C., *et al.*, (*ESA*) A.149

Blood, anticoagulants, aspirin, Inhibition of increase of blood thromboxane concentration by acetylsalicylic acid after release of tourniquet in lower extremity operations, Ojanen, R., *et al.*, (*ESA*) A.94

Blood, coagulation, Aprotinin does not decrease surgical bleeding and could promote arterial thrombosis in the pig: A prospective randomized, blind, study, Samama, C. M., *et al.*, (*ESA*) A.100

——, Blood requirements reduction in orthotopic liver transplantation with aprotinin, Monedero, P., *et al.*, (*ESA*) A.98

——, High dose aprotinin *versus* desmo-pressin acetate treatment in cardiac surgery, Hidalgo, F., *et al.*, (*ESA*) A.99

——, The combined prophylactic administration of H1 and H2 receptor blockers in the prevention of protamine related haemodynamic effects and the relation between antihistaminics-leucocytes and pulmonary vascular resistance, Durak, P., *et al.*, (*ESA*) A.95

——, The relationship between cardiopulmonary bypass related immunologic effects and complement, thromboxane and leucocyte parameters, Durak, P., *et al.*, (*ESA*) A.96

——, Use of aprotinine during cytoreductive surgery of ovarian cancer, Lequeau, F., *et al.*, (*ESA*) A.97

Blood, glucose, Neonatal glycemia: does the maternal i.v. fluid regimen during labor make a difference? Menigaux, C., *et al.*, (*ESA*) A.175

Blood, haematopoiesis, Effects of recombinant-human erythropoietin on postoperative transfusion requirements in subjects undergoing major orthopaedic surgery, Faris, P. P., *et al.*, (*ESA*) A.101

Blood, leucocytes, Effects of diazepam additives on the mononuclear phagocytic system, Catalá, J. C., *et al.*, (*ESA*) A.89

——, The combined prophylactic administration of H1 and H2 receptor blockers in the prevention of protamine related haemodynamic effects and the relation between antihistaminics-leucocytes and pulmonary vascular resistance, Durak, P., *et al.*, (*ESA*) A.95

——, The relationship between cardiopulmonary bypass related immunologic effects and complement, thromboxane and leucocyte parameters, Durak, P., *et al.*, (*ESA*) A.96

Blood, loss, Aprotinin does not decrease surgical bleeding and could promote arterial thrombosis in the pig: A prospective randomized, blind, study, Samama, C. M., *et al.*, (*ESA*) A.100

——, Blood requirements reduction in orthotopic liver transplantation with aprotinin, Monedero, P., *et al.*, (*ESA*) A.98

——, High dose aprotinin *versus* desmo-pressin acetate treatment in cardiac surgery, Hidalgo, F., *et al.*, (*ESA*) A.99

——, The effects of bupivacaine, mepivacaine and prilocaine on platelet aggregation, Bayhan, N., *et al.*, (*ESA*) A.123

——, Use of aprotinine during cytoreductive surgery of ovarian cancer, Lequeau, F., *et al.*, (*ESA*) A.97

Blood, platelets, Acute preoperative plasmapheresis during cardiac surgery, Armellin, G., *et al.*, (*ESA*) A.104

——, The effects of bupivacaine, mepivacaine and prilocaine on platelet aggregation, Bayhan, N., *et al.*, (*ESA*) A.123

Blood, replacement, Acute preoperative plasmapheresis during cardiac surgery, Armellin, G., *et al.*, (*ESA*) A.104

——, Blood requirements reduction in orthotopic liver transplantation with aprotinin, Monedero, P., *et al.*, (*ESA*) A.98

——, Effects of plasma volume substitution on right ventricle volumes and function using Elohes® and Plasmion®, Lepage, J. Y., *et al.*, (*ESA*) A.35

——, Effects of recombinant-human erythropoietin on postoperative transfusion requirements in subjects undergoing major orthopaedic surgery, Faris, P. P., *et al.*, (*ESA*) A.101

——, High dose aprotinin *versus* desmo-pressin acetate treatment in cardiac surgery, Hidalgo, F., *et al.*, (*ESA*) A.99

——, Preoperative autotransfusion in emergency surgery for spine trauma, Riou, B., *et al.*, (*ESA*) A.102

Blood, salvage, Acute preoperative plasmapheresis during cardiac surgery, Armellin, G., *et al.*, (*ESA*) A.104

——, Effects of postoperative auto-transfusion in spine surgery, Riou, B., *et al.*, (*ESA*) A.103

——, Preoperative autotransfusion in emergency surgery for spine trauma, Riou, B., *et al.*, (*ESA*) A.102

Blood, volume, A comparison between various hemodynamic parameters reflecting preload during traded hemorrhage in ventilated dogs, Preisman, S., *et al.*, (*ESA*) A.51

——, Effects of plasma volume substitution on right ventricle volumes and function using Elohes® and Plasmion®, Lepage, J. Y., *et al.*, (*ESA*) A.35

——, Glycine and its metabolites during and after intrauterine YAG laser surgery, Van Boven, M. J., *et al.*, (*ESA*) A.87

——, Prevention of acute tubular necrosis by volume loading in kidney transplantation, Mouquet, C., *et al.*, (*ESA*) A.82

——, Propofol/fentanyl-anesthesia in patients with highly depressed cardiac function, Rauch, H., *et al.*, (*ESA*) A.30

——, The systolic pressure variation predicts response to volume loading in patients ventilated after aortic surgery, Coriat, P., *et al.*, (*ESA*) A.38

——, Volume loading and hormonal factors in the prevention of acute tubular necrosis in kidney transplantation, Mouquet, C., *et al.*, (*ESA*) A.83

Brain, blood flow, Cerebral blood flow velocities (CBFV) during anaesthesia for gynaecological laparoscopic surgery, Granry, J. C., *et al.*, (*ESA*) A.32

——, Cerebral perfusion during obstructive sleep apnea (OSA), Bålfors, E., *et al.*, (*ESA*) A.62

——, EEG-monitoring during defibrillator-implantation: effects of repetitive cerebral ischemia on electric brain activity, Spies, C., *et al.*, (*ESA*) A.110

——, Midazolam prevents ketamine-induced stimulation of cerebral metabolism, Åkeson, J., *et al.*, (*ESA*) A.111

——, Sufentanil increases intracranial pressure in patients with head trauma, Albanese, J., *et al.*, (*ESA*) A.107

——, The choice of ECM rate could improve the neuroprotection during CPR, Iannuzzi, E., *et al.*, (*ESA*) A.195

——, Transcranial Doppler sonography: effect of propofol and thiopental in patients with brain tumors and brain injuries, Schregel, W., *et al.*, (*ESA*) A.105

Brain, electroencephalography, EEG-monitoring during defibrillator-implantation: effects of repetitive cerebral ischemia on electric brain activity, Spies, C., *et al.*, (*ESA*) A.110

Brain, evoked potentials, Accuracy of processed auditory evoked response in predicting movement during cardiac surgery, Kuppe, H., *et al.*, (*ESA*) A.31

——, Effects of intrathecal meperidine (MP), fentanyl (FN) and lidocaine (LD) on somatosensory (SSEP) and cortical motor (CMEP) evoked potentials in humans, Fernandez, S., *et al.*, (*ESA*) A.119

——, Nitrous oxide induced neuronal depression: modification through benzodiazepine receptors, Dzoljic, M., *et al.*, (*ESA*) A.112

Brain, GABA, Dexmedetomidine does not exercise its anesthetic action through GABA, Salonen, M., *et al.*, (*ESA*) A.113

Brain, injury, Transcranial Doppler sonography: effect of propofol and thiopental in patients with brain tumors and brain injuries, Schregel, W., *et al.*, (*ESA*) A.105

Brain, intracranial pressure, Effect of esmolol *versus* lidocaine on intracranial pressure and haemodynamic responses to laryngoscopy and intubation, Samaha, T., *et al.*, (*ESA*) A.118

——, Jugular bulb metabolic monitoring during hyperventilation in severe head trauma patients, De Deyne, C., *et al.*, (*ESA*) A.106

——, Sufentanil increases intracranial pressure in patients with head trauma, Albanese, J., *et al.*, (*ESA*) A.107

Brain, ischaemia, EEG-monitoring during defibrillator-implantation: effects of repetitive cerebral ischemia on electric brain activity, Spies, C., *et al.*, (*ESA*) A.110

——, Jugular bulb metabolic monitoring during hyperventilation in severe head trauma patients, De Deyne, C., *et al.*, (*ESA*) A.106

Brain, metabolism, Midazolam prevents ketamine-induced stimulation of cerebral metabolism, Åkeson, J., *et al.*, (*ESA*) A.111

Brain, saccadic eye movements, Evaluation of saccadic eye movements as an objective test during recovery from anesthesia, Paut, O., *et al.*, (*ESA*) A.10

Burkitt's lymphoma, Is Burkitt's lymphoma an etiology or a differential diagnosis of malignant hyperthermia? Lienhart, A., *et al.*, (*ESA*) A.93

Calcium channel block, nicardipine, Does nicardipine potentiate the neuromuscular block of atracurium? Bazin, J. E., *et al.*, (*ESA*) A.136

Calcium channel block, nifedipine, Effect of premedication with nifedipine on intraoperative hypothermia, Vassilieff, N., *et al.*, (*ESA*) A.71

Cancer, High dose oral morphine in cancer pain management, Radbruch, L., *et al.*, (*ESA*) A.212

——, Intranasal fentanyl for breakthrough cancer pain or incident pain, Striebel, W. H., *et al.*, (*ESA*) A.210

——, Intrathecal pain relief in terminally ill cancer patients at home, Wagemans, M. F. M., *et al.*, (*ESA*) A.213

——, Is Burkitt's lymphoma an etiology or a differential diagnosis of malignant hyperthermia? Lienhart, A., *et al.*, (*ESA*) A.93

——, Postoperative hypoxaemia: comparison of epidural and patient controlled analgesia, Spencer, A., *et al.*, (*ESA*) A.207

——, Transcranial Doppler sonography: effect of propofol and thiopental in patients with brain tumors and brain injuries, Schregel, W., *et al.*, (*ESA*) A.105

——, Treatment of cancer pain with morphine (MO)—A double blind study of extradural (ED) *versus* intramuscular (im) routes of administration, Nath, S., *et al.*, (*ESA*) 211–A

——, Use of aprotinine during cytoreductive surgery of ovarian cancer, Lequeau, F., *et al.*, (*ESA*) A.97

Carbon dioxide, measurement, Relationship between arterial $P\mathrm{co}_2$ (Pa_{CO_2}) and end tidal CO_2 (ETco_2) recorded through a laryngeal mask (LMA) in children breathing spontaneously, Van Obbergh, L. J., *et al.*, (*ESA*) A.164

Carbon dioxide, partial pressure, Is correlation of arterial and end-tidal carbon dioxide pressure during inhalation anaesthesia better with laryngeal mask as compared to face mask? Ivens, D., *et al.*, (*ESA*) A.17

——, Relationship between arterial $P\mathrm{co}_2$ (Pa_{CO_2}) and end tidal CO_2 (ETco_2) recorded through a laryngeal mask (LMA) in children breathing spontaneously, Van Obbergh, L. J., *et al.*, (*ESA*) A.164

——, Respiratory effects of laparoscopic cholecystectomy (preliminary data), Crea, M. A., *et al.*, (*ESA*) A.63

Cardiorespiratory system, effects, Abdominal wall retraction may decrease anaesthesiological risks of laparoscopic cholecystectomy, Vereczkey, Z., *et al.*, (*ESA*) A.64

——, Diaphragmatic function after bupivacaine cervical extradural analgesia for chronic pain therapy, Nyström, E., *et al.*, (*ESA*) A.65

——, Pulmonary and systemic vascular effects of isoproterenol, nitroglycerin and prostaglandin E1 early after cardiac operations in patients with pulmonary hypertension, Alvarez, J., *et al.*, (*ESA*) A.27

——, Respiratory effects of laparoscopic cholecystectomy (preliminary data), Crea, M. A., *et al.*, (*ESA*) A.63

——, The combined prophylactic administration of H1 and H2 receptor blockers in the prevention of protamine related haemodynamic effects and the relation between antihistaminics-leucocytes and pulmonary vascular resistance, Durak, P., *et al.*, (*ESA*) A.95

Cardiovascular system, effects, Does exogenous dopamine reverse cardiovascular depression induced by isoflurane during thoracic epidural blockade? Raner, C., *et al.*, (*ESA*) A.49

——, Effects of nitrous oxide (N_2O) on systemic haemodynamics, regional left ventricular (LV) function and incidence of myocardial ischaemia (MI) in vascular surgical patients with coronary artery disease (CAD), Hohner, P., *et al.*, (*ESA*) A.41

——, Local *versus* neurogenic vasodilator effects of desflurane and isoflurane in the small intestine, Sundeman, H., *et al.*, (*ESA*) A.50

Cardiovascular system, responses, Comparison of dobutamine with enoximone following open heart surgery in small children, Innes, P., *et al.*, (*ESA*) A.167

——, Dose dependent effects of oral medication with midazolam, Biro, P., *et al.*, (*ESA*) A.156

——, Echocardiographic study of the induction with a low-dose of sufentanil for coronary artery surgery, Bromberg, N., *et al.*, (*ESA*) A.28

——, Effect of esmolol *versus* lidocaine on intracranial pressure and haemodynamic responses to laryngoscopy and intubation, Samaha, T., *et al.*, (*ESA*) A.118

——, Effects of oral preoperative guanfacine on anesthetics requirements, Engelman, E., *et al.*, (*ESA*) A.144

——, Evaluation of cardiac function in ICU: right heart catheterization *vs* transesophageal echocardiography. Preliminary results, Vivien, B., *et al.*, (*ESA*) A.183

——, Influence of pneumoperitoneum and posture on hemodynamic and stress responses during anaesthesia for laparoscopic surgery, Odeberg, S., *et al.*, (*ESA*) A.34

——, Prevention of acute tubular necrosis by volume loading in kidney transplantation, Mouquet, C., *et al.*, (*ESA*) A.82

——, Tolerance of preoperative transesophageal echocardiography in patients scheduled for aortic surgery, Gosgnach, M., *et al.*, (*ESA*) A.21

Cat, Local *versus* neurogenic vasodilator effects of desflurane and isoflurane in the small intestine, Sundeman, H., *et al.*, (*ESA*) A.50

Cerebrospinal fluid, External ventricular CSF drains infections, Mahé, V., *et al.*, (*ESA*) A.109

Children, Clonidine in paediatric caudal anaesthesia, Jamali, S., *et al.*, (*ESA*) A.160

——, Comparison of dobutamine with enoximone following open heart surgery in small children, Innes, P., *et al.*, (*ESA*) A.167

——, Continuous monitoring of Sp_{O_2} during total intravenous anaesthesia with ketamine and spontaneous ventilation, Joly, L.-M., *et al.*, (*ESA*) A.58

——, Evaluation of the efficacy of forced-air warmer (Bair Hugger) during spinal surgery in children, Murat, I., *et al.*, (*ESA*) A.165

——, Neuromuscular blockade following mivacurium in children during N_2O–halothane, Orliaguet, G., *et al.*, (*ESA*) A.163

——, Propofol for tracheal intubation in paediatric outpatient anaesthesia, Montasser, A. M., (*ESA*) A.161

——, Relationship between arterial $P\mathrm{co}_2$ (Pa_{CO_2}) and end tidal CO_2 (ETco_2) recorded through a laryngeal mask (LMA) in children breathing spontaneously, Van Obbergh, L. J., *et al.*, (*ESA*) A.164

——, The pharmacokinetics of rocuronium in pediatric patients: a pooled data analysis, Meistelman, C., *et al.*, (*ESA*) A.138

——, Use of thoracic epidural block for perioperative analgesia in children, Entress, A. H., *et al.*, (*ESA*) A.158

Complications, accidents, Evaluation of systematic TEE in patients suspected of blunt chest trauma, Catoire, P., *et al.*, (*ESA*) A.192

——, Jugular bulb metabolic monitoring during hyperventilation in severe head trauma patients, De Deyne, C., *et al.*, (*ESA*) A.106

——, Sufentanil increases intracranial pressure in patients with head trauma, Albanese, J., *et al.*, (*ESA*) A.107

——, The part of rescue helicopters in large accidents and disasters, Wenker, O., (*ESA*) A.197

Complications, adult respiratory distress syndrome, Histology aspects of pulmonary barotrauma in critically ill patients with acute respiratory failure, Rouby, J. J., *et al.*, (*ESA*) A.181

——, Non invasive monitoring of CO_2 in patients with septic shock, Bodin, L., *et al.*, (*ESA*) A.191

Complications, alcohol abuse, Carbohydrate deficient transferrin: a new copredictor of alcoholism related postoperative complications? Heil, T., *et al.*, (*ESA*) A.88

Complications, aneurysm, Cardiac function in aneurysmal subarachnoid haemorrhage, Moulay, N., *et al.*, (*ESA*) A.108

——, Helicopter transportation of patients with symptomatic aortic aneurysms, Fellerter, P., *et al.*, (*ESA*) A.196

Complications, aortic rupture, Diagnosis of aortic rupture by transesophageal echocardiography (TEE), Goarin, J. P., *et al.*, (*ESA*) A.193

Complications, arthritis, Differential effects of specific delta and kappa opioid antagonists on the bidirectionnal effect of naloxone in arthritic rats, Cattaneo, I., *et al.*, (*ESA*) A.114

Complications, atelectasis, Recruitment of atelectasis during general anaesthesia: a CT-study, Rothen, H. U., *et al.*, (*ESA*) A.53

Complications, barotrauma, Histology aspects of pulmonary barotrauma in critically ill patients with acute respiratory failure, Rouby, J. J., *et al.*, (*ESA*) A.181

Complications, Burkitt's lymphoma, Is Burkitt's lymphoma an etiology or a differential diagnosis of malignant hyperthermia? Lienhart, A., *et al.*, (*ESA*) A.93

Complications, colitis, Measurement of sigmoid intramural pH during orthotopic liver transplantation, Auroy, Y., *et al.*, (*ESA*) A.76

Complications, death, A national database for intensive care medicine in Sweden, Karling, M., (*ESA*) A.8

Complications, embolism, Inhibition of increase of blood thromboxane concentration by acetylsalicylic acid after release of tourniquet in lower extremity operations, Ojanen, R., *et al.*, (*ESA*) A.94

——, Reassessment of bronchoalveolar lavage in the diagnosis of post traumatic pulmonary fat embolism, Mimoz, O., *et al.*, (*ESA*) A.180

——, Systemic gas embolism in pulmonary contusion diagnosed by transesophageal echocardiography, Saada, M., *et al.*, (*ESA*) A.194

Complications, endocardial endothelium damage, Endocardial endothelium modulates *in vivo* left ventricular performance, De Hert, S. G., *et al.*, (*ESA*) A.47

Complications, haemorrhage, Cardiac function in aneurysmal subarachnoid haemorrhage, Moulay, N., *et al.*, (*ESA*) A.108

Complications, head injury, Jugular bulb metabolic monitoring during hyperventilation in severe head trauma patients, De Deyne, C., *et al.*, (*ESA*) A.106

——, Sufentanil increases intracranial pressure in patients with head trauma, Albanese, J., *et al.*, (*ESA*) A.107

Complications, headache, Best Quincke point needle for Caesarean section, Lyons, G., (*ESA*) A.174

——, Epidural blood patch for treatment of postdural puncture headache, Rosenberg, P. H., *et al.*, (*ESA*) A.129

——, Prevention of acute tubular necrosis by volume loading in kidney transplantation, Mouquet, C., *et al.*, (*ESA*) A.82
——, Volume loading and hormonal factors in the prevention of acute tubular necrosis in kidney transplantation, Mouquet, C., *et al.*, (*ESA*) A.83
Kidney, function, Effects of desmopressin (DDAVP) supplementation in brain dead organ donors (BDOD) on early recipient renal function, Guesde, R., *et al.*, (*ESA*) A.79
——, Preoperative clonidine improves postoperative renal function in CABG patients, Kulka, P. J., *et al.*, (*ESA*) A.143
——, Renal blood flow and function relationship in recent renal transplantation in man, Jacob, L., *et al.*, (*ESA*) A.85
Kidney, lithotripsy, Propofol anaesthesia with spontaneous breathing for extracorporeal shock wave lithotripsy, Pasch, T., *et al.*, (*ESA*) A.153
Kidney, transplantation, Effects of desmopressin (DDAVP) supplementation in brain dead organ donors (BDOD) on early recipient renal function, Guesde, R., *et al.*, (*ESA*) A.79
——, Is the vasoconstrictive effect of cyclosporine mediated by endothelin in kidney transplantation? Mouquet, C., *et al.*, (*ESA*) A.84
——, Prevention of acute tubular necrosis by volume loading in kidney transplantation, Mouquet, C., *et al.*, (*ESA*) A.82
——, Renal blood flow and function relationship in recent renal transplantation in man, Jacob, L., *et al.*, (*ESA*) A.85
——, Total intravenous anaesthesia (TIVA) with propofol and alfentanil for renal transplantation, Kirvelä, M., *et al.*, (*ESA*) A.81
——, Volume loading and hormonal factors in the prevention of acute tubular necrosis in kidney transplantation, Mouquet, C., *et al.*, (*ESA*) A.83
Kidney, urine metabolites, Modification of the renin–aldosterone axis during orthotopic liver transplantation, De los Ríos, J., *et al.*, (*ESA*) A.75

Larynx, damage, Day 0 or day 3 laryngoscopy after thyroidectomy? Lacoste, L., *et al.*, (*ESA*) A.67
——, Direct, indirect or flexible laryngoscopy after thyroidectomy? Lacoste, L., *et al.*, (*ESA*) A.66
Larynx, laryngoscopy, Day 0 or day 3 laryngoscopy after thyroidectomy? Lacoste, L., *et al.*, (*ESA*) A.67
——, Direct, indirect or flexible laryngoscopy after thyroidectomy? Lacoste, L., *et al.*, (*ESA*) A.66
——, Effect of esmolol ***versus*** lidocaine on intracranial pressure and haemodynamic responses to laryngoscopy and intubation, Samaha, T., *et al.*, (*ESA*) A.118
——, Laryngeal function as assessed by tussometry following topical anaesthesia, Mahajan, R. P., *et al.*, (*ESA*) A.68
Larynx, laryngoscopy fibreoptic, Direct, indirect or flexible laryngoscopy after thyroidectomy? Lacoste, L., *et al.*, (*ESA*) A.66
Larynx, vocal cords, Concentration–effect relationship at the vocal cords and the adductor pollicis following rocuronium administration, Plaud, B., *et al.*, (*ESA*) A.141
——, Laryngeal function as assessed by tussometry following topical anaesthesia, Mahajan, R. P., *et al.*, (*ESA*) A.68
Liver, blood flow, The effect of dobutamine and norepinephrine on global and splanchnic O_2 consumption, Meier-Hellmann, A., *et al.*, (*ESA*) A.185
Liver, cirrhosis, Modification of the renin–aldosterone axis during orthotopic liver transplantation, De los Ríos, J., *et al.*, (*ESA*) A.75
——, Oxygen consumption is dependent upon oxygen delivery in cirrhotics undergoing liver transplantation, Piccinni, P., *et al.*, (*ESA*) A.78
Liver, metabolism, Influence of norepinephrine therapy on the oxygen supply and lactate extraction rate of the liver in the septic pig, Schäfer, R., *et al.*, (*ESA*) A.184
Liver, oxygen consumption, The effect of dobutamine and norepinephrine on global and splanchnic O_2 consumption, Meier-Hellmann, A., *et al.*, (*ESA*) A.185
Liver, transplantation, Blood requirements reduction in orthotopic liver transplantation with aprotinin, Monedero, P., *et al.*, (*ESA*) A.98
——, Changes in blood lactate, total body oxygen delivery and consumption during liver transplantation, Carrera, J., *et al.*, (*ESA*) A.77
——, Measurement of sigmoid intramural pH during orthotopic liver transplantation, Auroy, Y., *et al.*, (*ESA*) A.76
——, Modification of the renin–aldosterone axis during orthotopic liver transplantation, De los Ríos, J., *et al.*, (*ESA*) A.75
——, Oxygen consumption is dependent upon oxygen delivery in cirrhotics undergoing liver transplantation, Piccinni, P., *et al.*, (*ESA*) A.78
Lung, atelectasis, Recruitment of atelectasis during general anaesthesia: a CT-study, Rothen, H. U., *et al.*, (*ESA*) A.53
Lung, compliance, Influence of posture on the respiratory mechanics during anesthesia, Engelman, E., *et al.*, (*ESA*) A.56
——, The respiratory compliance in normal and obese subjects during anaesthesia, Mulazzi, D., *et al.*, (*ESA*) A.54
Lung, damage, Histology aspects of pulmonary barotrauma in critically ill patients with acute respiratory failure, Rouby, J. J., *et al.*, (*ESA*) A.181
——, Systemic gas embolism in pulmonary contusion diagnosed by transesophageal echocardiography, Saada, M., *et al.*, (*ESA*) A.194
Lung, function, Fiberoptic bronchoscopy in brain dead organ donors, Riou, B., *et al.*, (*ESA*) A.80
Lung, gas exchange, Cardiac output determined from pulmonary gas exchange, Österlund, B., *et al.*, (*ESA*) A.19
Lung, intravascular pressures, Pulmonary and systemic vascular effects of isoproterenol, nitroglycerin and prostaglandin E1 early after cardiac operations in patients with pulmonary hypertension, Alvarez, J., *et al.*, (*ESA*) A.27
Lung, lavage, Reassessment of bronchoalveolar lavage in the diagnosis of post traumatic pulmonary fat embolism, Mimoz, O., *et al.*, (*ESA*) A.180
Lung, transplantation, Fiberoptic bronchoscopy in brain dead organ donors, Riou, B., *et al.*, (*ESA*) A.80

Malignant hyperthermia, Exercise and malignant hyperthermia: family investigations, Kozak Ribbens, G., *et al.*, (*ESA*) A.92
——, Is Burkitt's lymphoma an etiology or a differential diagnosis of malignant hyperthermia? Lienhart, A., *et al.*, (*ESA*) A.93
Measurement techniques, arterial pressure, Clinical evaluation of the calibration of noninvasive continuous blood pressure measurement devices by means of oscillometric blood pressure measurements, de Jong, J. R., *et al.*, (*ESA*) A.15
Measurement techniques, carbon dioxide, Non invasive monitoring of CO_2 in patients with septic shock, Bodin, L., *et al.*, (*ESA*) A.191
Measurement techniques, cardiac output, Cardiac output determined from pulmonary gas exchange, Österlund, B., *et al.*, (*ESA*) A.19
——, Cardiac output(CO) measurement: comparison of esophageal Doppler (ED) *vs* thermodilution (TD), Lefrant, J. Y., *et al.*, (*ESA*) A.18
Measurement techniques, Doppler echocardiography, Cardiac output (CO) measurement: comparison of esophageal Doppler (ED) *vs* thermodilution (TD), Lefrant, J. Y., *et al.*, (*ESA*) A.18
Measurement techniques, neuromuscular block, Comparison between double-burst stimulation and 50, 100 Hz tetanic fade during spontaneous recovery of vecuronium induced neuromuscular blockade, Baurain, M. J., *et al.*, (*ESA*) A.133
Measurement techniques, oximeters, Technical aspects of jugular bulb oximetry, De Deyne, C., *et al.*, (*ESA*) A.16
Measurement techniques, plethysmography, The effects of epidural and spinal anesthesia on the changes in the plethysmographic signal in the lower and upper limbs, Preisman, S., *et al.*, (*ESA*) A.124
Measurement techniques, spectral analysis, Accuracy of processed auditory evoked response in predicting movement during cardiac surgery, Kuppe, H., *et al.*, (*ESA*) A.31
Measurement techniques, thermodilution, Cardiac output determined from pulmonary gas exchange, Österlund, B., *et al.*, (*ESA*) A.19
——, Cardiac output (CO) measurement: comparison of esophageal Doppler (ED) *vs* thermodilution (TD), Lefrant, J. Y., *et al.*, (*ESA*) A.18
Measurement techniques, tussometry, Laryngeal function as assessed by tussometry following topical anaesthesia, Mahajan, R. P., *et al.*, (*ESA*) A.68

Measurement techniques, ultrasound, Cerebral blood flow velocities (CBFV) during anaesthesia for gynaecological laparoscopic surgery, Granry, J. C., *et al.*, (*ESA*) A.32
——, Renal blood flow and function relationship in recent renal transplantation in man, Jacob, L., *et al.*, (*ESA*) A.85
——, Transcranial Doppler sonography: effect of propofol and thiopental in patients with brain tumors and brain injuries, Schregel, W., *et al.*, (*ESA*) A.105
Membrane, nerve, Nitrous oxide induced neuronal depression: modification through benzodiazepine receptors, Dzoljic, M., *et al.*, (*ESA*) A.112
Memory, Flumazenil facilitates intraoperative arousal in scoliosis surgery, Koscielniak-Nielsen, Z. J., *et al.*, (*ESA*) A.157
——, Midazolam premedication: a forensic approach to pharmacokinetics and amnesia, Motsch, J., *et al.*, (*ESA*) A.155
Metabolism, free radicals, Propofol (2,6 diisopropylphenol) as an antioxidant *in-vitro*: a dose response study, Bennett, S., *et al.*, (*ESA*) A.152
Metabolism, glucose, Isoflurane inhibits Ca^{2+}-induced insulin secretion from electrically permeabilised islets of Langerhans, Desborough, J. P., *et al.*, (*ESA*) A.91
——, Neonatal glycemia: does the maternal i.v. fluid regimen during labor make a difference? Menigaux, C., *et al.*, (*ESA*) A.175
Metabolism, glycine, Glycine and its metabolites during and after intrauterine YAG laser surgery, Van Boven, M. J., *et al.*, (*ESA*) A.87
Metabolism, lactate, Changes in blood lactate, total body oxygen delivery and consumption during liver transplantation, Carrera, J., *et al.*, (*ESA*) A.77
——, Influence of norepinephrine therapy on the oxygen supply and lactate extraction rate of the liver in the septic pig, Schäfer, R., *et al.*, (*ESA*) A.184
——, Jugular bulb metabolic monitoring during hyperventilation in severe head trauma patients, De Deyne, C., *et al.*, (*ESA*) A.106
——, Sensitivity and specificity of mechanical and electrocardiographic myocardial ischaemia (MI) monitoring techniques, Hohner, P., *et al.*, (*ESA*) A.26
——, The use of the CUSUM plot for determination of myocardial ischaemia threshold during atrial pacing in patients with coronary artery disease, Reiz, S., *et al.*, (*ESA*) A.24
Metabolism, midazolam, Midazolam premedication: a forensic approach to pharmacokinetics and amnesia, Motsch, J., *et al.*, (*ESA*) A.155
Metabolism, oxygen consumption, Influence of norepinephrine therapy on the oxygen supply and lactate extraction rate of the liver in the septic pig, Schäfer, R., *et al.*, (*ESA*) A.184
Metabolism, protein, Effect of recombinant human growth hormone (HGH) on protein metabolism in surgical patients, Carli, F., *et al.*, (*ESA*) A.86
Microcirculation, Influence of N-acetylcysteine on O_2 consumption and gastric intramucosal pH in septic patients, Spies, C., *et al.*, (*ESA*) A.186
Model, acute pain service, Organization of acute pain services—a low-cost model, Rawal, N., (*ESA*) A.199
Model, computer simulation, Computer-controlled syringe pump improves safety of pharmacokinetic models, Duranteau, R., *et al.*, (*ESA*) A.148
Model, mathematical, Evaluation in intensive care of the fraction area change obtained by automatic border detection, Liu, N., *et al.*, (*ESA*) A.25
——, The use of the CUSUM plot for determination of myocardial ischaemia threshold during atrial pacing in patients with coronary artery disease, Reiz, S., *et al.*, (*ESA*) A.24
Model, pharmacokinetic, Computer-controlled syringe pump improves safety of pharmacokinetic models, Duranteau, R., *et al.*, (*ESA*) A.148
——, Determination of a pharmacokinetic model for propofol induction of anaesthesia, Viviand, X., *et al.*, (*ESA*) A.150
Monitoring, angiography, Dipyridamole-TEE and 24 h Holter-ECG as preoperative screening tests for coronary artery disease in patients with abdominal aortic aneurysm, Östman, M., *et al.*, (*ESA*) A.22
——, Does routine preoperative coronary angiography modify outcome after aortic surgery? Gosgnach, M., *et al.*, (*ESA*) A.6
——, Indications for coronary revascularisation in vascular surgical patients, Gosgnach, M., *et al.*, (*ESA*) A.5
Monitoring, carbon dioxide, Non invasive monitoring of CO_2 in patients with septic shock, Bodin, L., *et al.*, (*ESA*) A.191
Monitoring, computerized, Continuous monitoring of the ventilatory mechanics during anaesthesia & intensive care, Py, C., *et al.*, (*ESA*) A.57
——, Evaluation in intensive care of the fraction area change obtained by automatic border detection, Liu, N., *et al.*, (*ESA*) A.25
——, Sensitivity and specificity of mechanical and electrocardiographic myocardial ischaemia (MI) monitoring techniques, Hohner, P., *et al.*, (*ESA*) A.26
——, The use of the CUSUM plot for determination of myocardial ischaemia threshold during atrial pacing in patients with coronary artery disease, Reiz, S., *et al.*, (*ESA*) A.24
Monitoring, depth of anaesthesia, Accuracy of processed auditory evoked response in predicting movement during cardiac surgery, Kuppe, H., *et al.*, (*ESA*) A.31
Monitoring, echocardiography, Cardiac function in aneurysmal subarachnoid haemorrhage, Moulay, N., *et al.*, (*ESA*) A.108
——, Determinants of systolic pressure variation in patients ventilated after vascular surgery, Beaussier, M., *et al.*, (*ESA*) A.37
——, Diagnosis of aortic rupture by transesophageal echocardiography (TEE), Goarin, J. P., *et al.*, (*ESA*) A.193
——, Dipyridamole-TEE and 24 h Holter-ECG as preoperative screening tests for coronary artery disease in patients with abdominal aortic aneurysm, Östman, M., *et al.*, (*ESA*) A.22
——, Echocardiographic study of the induction with a low-dose of sufentanil for coronary artery surgery, Bromberg, N., *et al.*, (*ESA*) A.28
——, Evaluation in intensive care of the fraction area change obtained by automatic border detection, Liu, N., *et al.*, (*ESA*) A.25
——, Evaluation of cardiac function in ICU: right heart catheterization *vs* transesophageal echocardiography. Preliminary results, Vivien, B., *et al.*, (*ESA*) A.183
——, Evaluation of systematic TEE in patients suspected of blunt chest trauma, Catoire, P., *et al.*, (*ESA*) A.192
——, Sensitivity and specificity of mechanical and electrocardiographic myocardial ischaemia (MI) monitoring techniques, Hohner, P., *et al.*, (*ESA*) A.26
——, Systemic gas embolism in pulmonary contusion diagnosed by transesophageal echocardiography, Saada, M., *et al.*, (*ESA*) A.194
——, Tolerance of preoperative transesophageal echocardiography in patients scheduled for aortic surgery, Gosgnach, M., *et al.*, (*ESA*) A.21
Monitoring, electrocardiography, Cardiac function in aneurysmal subarachnoid haemorrhage, Moulay, N., *et al.*, (*ESA*) A.108
——, Dipyridamole-TEE and 24 h Holter-ECG as preoperative screening tests for coronary artery disease in patients with abdominal aortic aneurysm, Östman, M., *et al.*, (*ESA*) A.22
——, Mechanisms of ECG changes during caesarean section (CS)—a hypothesis, Svanström, M., *et al.*, (*ESA*) A.177
——, Sensitivity and specificity of mechanical and electrocardiographic myocardial ischaemia (MI) monitoring techniques, Hohner, P., *et al.*, (*ESA*) A.26
Monitoring, electroencephalography, EEG-monitoring during defibrillator-implantation: effects of repetitive cerebral ischemia on electric brain activity, Spies, C., *et al.*, (*ESA*) A.110
Monitoring, electro-oculogram, Evaluation of saccadic eye movements as an objective test during recovery from anesthesia, Paut, O., *et al.*, (*ESA*) A.10
Monitoring, evoked potentials, Accuracy of processed auditory evoked response in predicting movement during cardiac surgery, Kuppe, H., *et al.*, (*ESA*) A.31
Monitoring, oxygen, Continuous monitoring of Sp_{O_2} during total intravenous anaesthesia with ketamine and spontaneous ventilation, Joly, L.-M., *et al.*, (*ESA*) A.58
——, Hypoxic events after general anaesthesia in the recovery room, Degasperi, D., *et al.*, (*ESA*) A.59
——, Technical aspects of jugular bulb oximetry, De Deyne, C., *et al.*, (*ESA*) A.16
Monitoring, spirometry, Continuous spirometry: an aid in the intraoperative respiratory monitoring—case reports, Bardoczky, G., *et al.*, (*ESA*) A.55
Monitoring, sympathetic block, The effects of epidural and spinal anesthesia on the changes in the plethysmographic signal in the lower and upper limbs, Preisman, S., *et al.*, (*ESA*) A.124
Monitoring, vectorcardiography, Sensitivity and specificity of mechanical and electrocardiographic myocardial ischaemia (MI) monitoring techniques, Hohner, P., *et al.*, (*ESA*) A.26
——, The use of the CUSUM plot for determination of

myocardial ischaemia threshold during atrial pacing in patients with coronary artery disease, Reiz, S., *et al.*, (*ESA*) A.24
Monitoring, ventilation, Continuous monitoring of the ventilatory mechanics during anaesthesia & intensive care, Py, C., *et al.*, (*ESA*) A.57
Muscle cardiac, contractility, Endocardial endothelium modulates *in vivo* left ventricular performance, De Hert, S. G., *et al.*, (*ESA*) A.47
——, Influence of cervicothoracic epidural anaesthesia (C-TEA) on left ventricular (LV) contractility—an experimental study in pigs with autonomous blockade, Reiz, S., *et al.*, (*ESA*) A.52
Muscle skeletal, diaphragm, Diaphragmatic function after bupivacaine cervical extradural analgesia for chronic pain therapy, Nyström, E., *et al.*, (*ESA*) A.65

Neonates, Extracorporeal membrane oxygenation for postoperative cardiac support in newborn infants: first clinical data, Marcassa, A., *et al.*, (*ESA*) A.168
——, Neonatal glycemia: does the maternal i.v. fluid regimen during labor make a difference? Menigaux, C., *et al.*, (*ESA*) A.175
Nerve, membrane, Nitrous oxide induced neuronal depression: modification through benzodiazepine receptors, Dzoljic, M., *et al.*, (*ESA*) A.112
Neuromuscular block, antagonism, Reversal of vecuronium induced neuromuscular blockade: No effects of atropine administration timing, Baurain, M. J., *et al.*, (*ESA*) A.134
Neuromuscular block, atracurium, Does nicardipine potentiate the neuromuscular block of atracurium? Bazin, J. E., *et al.*, (*ESA*) A.136
——, Monitoring the onset of neuromuscular blockade at the orbicularis oculi can predict good intubating conditions when using $2 \times ED_{95}$ of atracurium, Debaene, B., *et al.*, (*ESA*) A.142
——, Neostigmine antagonism of neuromuscular blockade induced by mivacurium, vecuronium and atracurium, Dernovoi, B. S., *et al.*, (*ESA*) A.137
——, Priming of atracurium with magnesium, Lampl, E., *et al.*, (*ESA*) A.139
——, Supra-additivity between atracurium and vecuronium, Meretoja, O. A., *et al.*, (*ESA*) A.140
Neuromuscular block, measurement of response, Can repetition of high frequencies stimuli alter the value of 50 and 100 Hz tetanic fade during vecuronium induced neuromuscular blockade? Baurain, M. J., *et al.*, (*ESA*) A.135
——, Comparison between double-burst stimulation and 50, 100 Hz tetanic fade during spontaneous recovery of vecuronium induced neuromuscular blockade, Baurain, M. J., *et al.*, (*ESA*) A.133
——, Monitoring the onset of neuromuscular blockade at the orbicularis oculi can predict good intubating conditions when using $2 \times ED_{95}$ of atracurium, Debaene, B., *et al.*, (*ESA*) A.142
Neuromuscular block, mivacurium, Neostigmine antagonism of neuromuscular blockade induced by mivacurium, vecuronium and atracurium, Dernovoi, B. S., *et al.*, (*ESA*) A.137
——, Neuromuscular blockade following mivacurium in children during N_2O–halothane, Orliaguet, G., *et al.*, (*ESA*) A.163
Neuromuscular block, potentiation, Does nicardipine potentiate the neuromuscular block of atracurium? Bazin, J. E., *et al.*, (*ESA*) A.136
Neuromuscular block, priming, Priming of atracurium with magnesium, Lampl, E., *et al.*, (*ESA*) A.139
Neuromuscular block, recovery, Can repetition of high frequencies stimuli alter the value of 50 and 100 Hz tetanic fade during vecuronium induced neuromuscular blockade? Baurain, M. J., *et al.*, (*ESA*) A.135
——, Comparison between double-burst stimulation and 50, 100 Hz tetanic fade during spontaneous recovery of vecuronium induced neuromuscular blockade, Baurain, M. J., *et al.*, (*ESA*) A.133
——, Neostigmine antagonism of neuromuscular blockade induced by mivacurium, vecuronium and atracurium, Dernovoi, B. S., *et al.*, (*ESA*) A.137
Neuromuscular block, rocuronium, Concentration–effect relationship at the vocal cords and the adductor pollicis following rocuronium administration, Plaud, B., *et al.*, (*ESA*) A.141
——, The pharmacokinetics of rocuronium in pediatric patients: a pooled data analysis, Meistelman, C., *et al.*, (*ESA*) A.138
Neuromuscular block, vecuronium, Can repetition of high frequencies stimuli alter the value of 50 and 100 Hz tetanic fade during vecuronium induced neuromuscular blockade? Baurain, M. J., *et al.*, (*ESA*) A.135
——, Comparison between double-burst stimulation and 50, 100 Hz tetanic fade during spontaneous recovery of vecuronium induced neuromuscular blockade, Baurain, M. J., *et al.*, (*ESA*) A.133
——, Neostigmine antagonism of neuromuscular blockade induced by mivacurium, vecuronium and atracurium, Dernovoi, B. S., *et al.*, (*ESA*) A.137
——, Reversal of vecuronium induced neuromuscular blockade: No effects of atropine administration timing, Baurain, M. J., *et al.*, (*ESA*) A.134
——, Supra-additivity between atracurium and vecuronium, Meretoja, O. A., *et al.*, (*ESA*) A.140

Oxygen, consumption, Changes in blood lactate, total body oxygen delivery and consumption during liver transplantation, Carrera, J., *et al.*, (*ESA*) A.77
——, Influence of N-acetylcysteine on O_2 consumption and gastric intramucosal pH in septic patients, Spies, C., *et al.*, (*ESA*) A.186
——, Oxygen consumption is dependent upon oxygen delivery in cirrhotics undergoing liver transplantation, Piccinni, P., *et al.*, (*ESA*) A.78
——, The effect of dobutamine and norepinephrine on global and splanchnic O_2 consumption, Meier-Hellmann, A., *et al.*, (*ESA*) A.185
Oxygen, delivery systems, Extracorporeal membrane oxygenation for postoperative cardiac support in newborn infants: first clinical data, Marcassa, A., *et al.*, (*ESA*) A.168
Oxygen, saturation, Continuous monitoring of Sp_{O_2} during total intravenous anaesthesia with ketamine and spontaneous ventilation, Joly, L.-M., *et al.*, (*ESA*) A.58
——, Hypoxic events after general anaesthesia in the recovery room, Degasperi, D., *et al.*, (*ESA*) A.59

BRITISH JOURNAL OF ANAESTHESIA

VOLUME 70, No. 1 JANUARY 1993

EDITORIAL I

HOW LONG SHOULD PATIENTS FAST BEFORE SURGERY? TIME FOR NEW GUIDELINES

"While it is desirable that there should be no solid matter in the stomach when chloroform is administered, it will be found very salutary to give a cup of tea or beef-tea about two hours previously." This sensible advice was given by Joseph, Baron Lister, in Holmes' *System of Surgery* in 1883. Why is the *British Journal of Anaesthesia* publishing a paper [1] in this issue, some 110 years later, offering the same advice but with an implication that this is something revolutionary? In the intervening years, concepts of "nil by mouth (or, in North American NPO) after midnight", or fluid restriction for a minimum period of time (usually 4–6 h, but many patients exceed this, encouraged by their doctors who believe longer is better), before an anaesthetic (either regional or general), have evolved. While none would argue that food should be ingested immediately before an anaesthetic, it is not clear where the idea of prolonged fluid restriction originated [2]. However, many anaesthetists assume that fluid deprivation protects patients against the risk of aspiration of acid gastric contents into the lungs, which may lead to the development of Mendelson's syndrome [3].

Mendelson [3] reviewed retrospectively the case notes of 44016 pregnancies in his hospital from 1932 to 1945. There were 66 cases of aspiration of stomach contents into the lungs (incidence 0.15%). In 45 cases, the aspirated material was recorded: 40 were liquid and, although the patients developed the characteristic chest radiograph changes which now bear Mendelson's name, there were no deaths; five patients inhaled solid material and died, in Mendelson's opinion from "suffocation". In the same paper, he showed elegantly that human acid vomitus injected into the trachea of rabbits caused the same chest radiograph changes he had observed in his patients. However, when he neutralized the vomitus, the radiographic changes did not occur. Solid material introduced into the rabbit's trachea caused either partial obstruction with ensuing massive atelectasis, or complete obstruction and suffocation. As a result of his observations, Mendelson offered the following advice in 1946: no oral feeding during labour—i.v. fluids should be given; wider use of local anaesthesia; alkalinization and emptying of the stomach before general anaesthesia; competent administration of general anaesthesia with full appreciation of the dangers of aspiration during induction and recovery; and the use of tracheal intubation. These tenets form the basis of obstetric anaesthesia today. A question remains, why did none of Mendelson's patients die after inhaling liquid acid gastric contents? In contrast, pregnant patients who inhaled liquid gastric contents in association with general anaesthesia and died have been detailed with depressing regularity by the triennial *Confidential Enquiry into Maternal Mortality* in Great Britain over the past 20 years; similarly, in non-pregnant adult patients and children, national and international surveys have described fatal pulmonary aspiration. However, it seems likely that these deaths relate more to the presence of risk factors such as gastrointestinal obstruction, head injury, depressed level of consciousness caused by drugs and repeated attempts at tracheal intubation and hypoxia with aspiration as a secondary event, or the use of positive pressure ventilation after aspiration, rather than to the acid material itself [4–7].

The next part of the story follows Mendelson's suggestion of alkalinizing the stomach. The availability of potent H_2 receptor blocking drugs [8] seemed the answer to the commonly quoted patient at risk of developing acid aspiration (Mendelson's) syndrome should they inhale their gastric contents, of a volume greater than 25 ml and pH less than 2.5, at induction of anaesthesia. It is worth noting that these figures are extrapolated from unpublished observations in Rhesus monkeys and cannot be tested ethically in humans. Nevertheless, most investigators have used these criteria of risk when assessing means of altering the gastric environment. Although H_2 receptor blockers are extremely effective in reducing gastric volume and increasing its pH, they do not produce this effect in every patient [8, 9]. Therefore administration of H_2 receptor blockers alone does not guarantee a safe gastric environment. However, two exciting observations emerged from these and related studies [10–12]. First, prolonged fluid deprivation was associated with increasing gastric volume and decreasing pH. Second, ingestion of fluid (water, coffee or juice) associated with either an increase in gastric volume (indeed, in some patients the volume decreased) or a significant change in pH (in some patients, pH increased). It would seem, therefore, that, far from protecting the patient, withholding fluid may be harmful in terms of both an adverse effect on the gastric environment and other indices of morbidity [13, 14], whereas administration is potentially beneficial.

Many investigators have examined the question of how long patients should fast. The basic method of study is outlined well by Phillips, Hutchinson and Davidson [1] in the present issue. Five, 4, 3 and now

2 h have been shown to be little different with respect to ingestion of modest quantities of fluid (usually 150–300 ml) in both adults and children undergoing elective operations [1, 15–19]. These findings are hardly surprising when one considers that the normally functioning stomach can dispose of much greater fluid loads than any studied so far with a half-life of about 10–20 min [20]. It is important to stress that the patients in the studies described here have been healthy and undergoing elective surgery, and those with gastrointestinal disease or taking drugs which affect intestinal function have been excluded. Fluid administered before premedication is tolerated well [1, 21], but the effects of opioids on delaying gastric emptying have precluded studies after premedication.

The question of administration of fluid to emergency patients remains unresolved. One could argue that, having decided that an operation cannot be postponed, and knowing that there is no method which can reliably empty the stomach, any factor which might reduce gastric volume or acidity or dilute solid material should be tried, as this could prevent either respiratory obstruction or Mendelson's syndrome, should pulmonary aspiration occur. In contrast, increasing the stomach content when trauma, drugs or illness have slowed emptying may invoke vomiting or regurgitation and thus lead to an increased risk of pulmonary aspiration. One would not advocate abandoning rapid sequence induction of general anaesthesia with cricoid pressure, awake tracheal intubation if indicated, or the use of non-particulate antacids or H_2 receptor blockers for emergency anaesthesia in patients "with a full stomach", but we should determine if prior oral fluid administration should be part of such patient preparation. In addition, what evidence is there that the prolonged fast inflicted routinely on these patients is beneficial? One can be sure that the investigation of these matters will not be straightforward. Ethics Committees agonized long and hard over many of the studies described in the investigation of elective patients and, to their shame, some journals refused publication of the early results on ethical grounds. Tackling the issue of emergency operations will require careful planning, but should be done in the further interest of patient wellbeing.

Returning to elective operations, which concern the vast majority of patients requiring an anaesthetic, it is clear that "nil by mouth after midnight" should be abandoned. In its place, there should be agreement by anaesthetists, surgeons and nurses on guidelines that both day-case and inpatients may take, if they wish, clear fluids by mouth up to 3 h before surgery. This allows for the vagaries of operating lists and should not lead to cancellation of procedures for patients who overstep the mark, merely some rescheduling. The way has been led by a Canadian teaching hospital which modified its guidelines in 1988 to recommend a 3-h fast period for elective surgical patients [22]. The new guidelines have been well received [J. R. Maltby—personal communication]. The fear of some anaesthetists that, if the absolute fasting rule were relaxed, patients could not be trusted to drink only clear fluids but would feel free to eat and drink anything they wished, has not been fulfilled. Patients do occasionally admit to having eaten a full meal. The frequency is no greater than before the change in guidelines and the patient's usual explanation is that no instructions were given; whether there are clerical errors or the patient has not read the instructions in these instances is uncertain. Such occasions are rare. Two follow-up studies of day-case and inpatients confirmed that there was no difference in gastric fluid volume or pH between those patients who were allowed to drink and those who fasted from midnight [23, 24]. Anaesthetic organizations within the United Kingdom should follow the Canadian example. We should not have to wait a further 110 years for change. "Those who do not learn from history will be forced to relive it" [George Santayana (1863–1952)].

EDITORIAL II

POSTOPERATIVE ANALGESIA IN CHILDREN

The recurring challenge of postoperative pain control in children is examined again in a study published in this issue of the Journal [1]. There are well known difficulties in this area: for example, assessment of pain in preverbal and preschool children, measurement of its intensity in this age group and of the relief gained from therapeutic interventions [2]. Recording and assessment of postoperative pain relief are recommended by the *Report of the Joint College Working Party on Pain after Surgery* [3]. However, detailed consistent assessment can be made only if there are available trained staff who are familiar with the behavioural and subjective effects of pain in children, in a suitable environment [4].

Several techniques have been developed recently in an attempt to improve upon traditional i.m. administration of opioids in children. I.v. infusion of opioids has been advocated [5], but the technique has not achieved widespread favour, possibly because of reluctance to use a method which in adults had a reputation for producing respiratory depression and episodic desaturation, particularly during sleep [6–8]. In addition, many anaesthetists regard the use of i.v. infusion techniques as an indication for postoperative care in an intensive care unit (ICU) or high dependency unit (HDU), or a nurse to patient staffing ratio of 2:1 in a dedicated postoperative ward. Such facilities are not always available, but the absence of an HDU has been highlighted recently as a factor in perioperative morbidity [9] and this may act as an impetus for improvement.

Curiously, there are few reports of respiratory depression in children after i.v. opioid infusions. Wolf and Hughes found significantly decreased ventilatory frequencies and oxygen saturation in a group of children given i.v. opioids [1], but this was not clinically important and other investigators found that an infusion of papaveretum 23 $\mu g\ kg^{-1}\ h^{-1}$ in 29 infants aged up to 6 months resulted in only one episode of respiratory depression [10]. However, the number of patients exposed to this technique to date is small compared with the number of adults for whom data are available, so these studies should not be taken as an indication that the technique is safe.

Monitoring of ventilatory frequency has been shown to be an insensitive index of the likelihood of respiratory depression; pulse oximetry should also be used when i.v. infusions are used in the spontaneously breathing child [11]. Continuous monitoring and frequent observation are essential safety measures [10] and therefore the appropriate environment is likely to be one in which adequate staffing ratios and HDU facilities exist.

Patient controlled analgesia (PCA) has been used in children older than 6 yr in both the U.S.A. [12] and the U.K. [13]. However, there are many details of technique which require clarification before PCA becomes a generally accepted technique: for example, what is the best opioid?; may the activating device for a PCA devised for adults be modified appropriately for children with small hands?; what is the appropriate lockout time?; does a background infusion provide superior analgesia compared with a bolus-alone technique? In adults, the use of a background infusion has been shown by some workers to produce no improvement in analgesia [14] and its routine use has been questioned [15]. The answer to these questions on PCA in children will require carefully designed clinical studies and it is fortunate that the recently published Department of Health guidelines on local research Ethics Committees chose to modify the draft proposal that non-therapeutic research in children should be abandoned [16].

Regional analgesia provides excellent analgesia for a relatively short period of time and is particularly appropriate in orthopaedic and lower abdominal surgery for control of postoperative pain [17]. Wolf and Hughes noted similar degrees of analgesia in a comparison of extradural bupivacaine by infusion with i.v. morphine [1]. However, regional anaesthetic techniques do possess some disadvantages: in the case of caudal extradural blocks, urinary retention has been reported in up to 65% of patients [18] and persistent motor block may occur in up to 30% [19]. More extensive blocks may result in total absence of sensation over large areas and this may be confusing to children and lead to restlessness. This side effect was noted in up to 19% of children given extradural bupivacaine [1]. Wolf and Hughes have suggested that i.v. morphine may be preferable as a sole analgesic or adjuvant in children who are likely to be overactive after surgery [1]. When some type of sedation is added to a local anaesthetic regimen in young children, particular care should be exercised to restrict the dosage of opioid as the balance of pain and respiratory depression may be disturbed [20].

It is stated frequently that one of the major reasons for avoiding i.m. administration of opioids in children is the associated pain of injection. However, attempts to avoid i.m. injections in children have resulted in a fatal outcome as a result of an inappropriate alternative prescription using the rectal route of administration [21]. Subcutaneous insertion of a cannula represents one method of obviating repeated i.m. injections. A cannula is placed at the time of anaesthesia, covered with a sterile dressing and flushed with heparinized saline in the postoperative period [22]. The cannula may be used for administration of s.c. morphine on an as-required basis as the sole method of providing analgesia or in reduced dosage to supplement regional anaesthetic techniques.

A phenomenon of late postoperative pain has been described with which postoperative pain worsens between 12 and 24 h after anaesthesia, either as a result of regression of a local anaesthetic block or possibly by elimination of drugs given during anaesthesia or for premedication. Drugs without respiratory depressant effects may be used to overcome this problem, for example regular administration of a non-steroidal analgesic drug (NSAID) with morphine. Ibuprofen has a short half-life but regular 8-hourly rectal administration was shown to reduce morphine requirements by 19% after abdominal hysterectomy [23] and rectal diclofenac has been shown to provide good analgesia in children after discharge from hospital after minor surgery [24]. The rectal route avoids painful i.m. injections with diclofenac, but unfortunately the suppositories of this drug are available in strengths of 12.5 mg and 100 mg, whereas many children require a dose intermediate between these two. Another method of extending analgesia is to combine opioids with local anaesthetic drugs in an extradural bolus or infusion technique [25]. This technique has been used in children and shown to be effective [26], although it was suggested that postoperative nursing of patients given combined local and opioid extradural infusions should take place in an HDU or extended recovery ward [27].

There have been several advances in recent years in the management of postoperative pain in adults. It is now evident that the problem of postoperative pain in children has also become an important issue. Whilst many techniques such as PCA may be used in older children, and it is gratifying to see the introduction of such regimens, there is still considerable scope for advances in pain therapy in infants and younger children.

PREOPERATIVE DRINKING DOES NOT AFFECT GASTRIC CONTENTS

S. PHILLIPS, S. HUTCHINSON AND T. DAVIDSON

SUMMARY

We have compared the effect of allowing free clear fluids until the time of oral premedication with conventional preoperative fasting. In a prospective, randomized trial, the residual volume and pH of gastric contents after induction of anaesthesia were measured in 100 elective surgical patients allocated randomly to a group in whom the intake of free clear fluids up to the time of premedication was measured (mean 388 ml in 6 h before surgery) or a control group who were fasted for 6 h. Preoperative drinking did not affect either mean (SD) residual gastric volume (22 (21) ml in the study group vs *19 (16) ml in the control group) or pH (study group 2.64 (1.57)* vs *control group 2.26 (1.45)). The study group experienced less preoperative thirst. Problems with aspiration or regurgitation were not encountered. We believe that allowing elective surgical patients to drink clear fluids until 2 h before anaesthesia may enhance patient comfort without compromising safety.* (Br. J. Anaesth. 1993; **70**: 6–9)

KEY WORDS

Gastrointestinal tract: fasting, gastric volume, preoperative fluid intake.

It is accepted widely that the risk of Mendelson's syndrome is reduced by minimizing the volume and increasing the pH of the gastric contents. To minimize the residual gastric volume (RGV), patients have been fasted traditionally for 4–6 h before surgery. This fasting interval is standard practice [1–3], but is not in keeping with the physiology of gastric emptying. A light meal leaves the stomach in 1.5–3 h and clear fluids almost immediately [1, 4]. Thus the conventional fast may be over-cautious, and reducing the fasting time may not increase the risk of pulmonary aspiration.

The preoperative fast is unpleasant for patients, who complain frequently of thirst and dry mouth. This is especially so in hot weather, when antisialagogue premedication has been prescribed and when theatre delays and cancellations occur. The ensuing dehydration may make anaesthesia more hazardous and contributes to perioperative morbidity [5–7].

Several workers have questioned the need for the conventional preoperative fasting period [8, 9]. In children, allowing clear fluid ingestion up to 2 h before surgery does not affect the volume or pH of gastric contents [10–12]. In adolescents, unlimited fluid ingestion until 3 h before surgery decreased thirst and did not affect gastric contents [13]. In adult practice, the same findings have not been documented in any controlled study. The incidence of aspiration pneumonitis is low [14] and appears to be unrelated to the gastric volume [15]. The ingestion of 150 ml of orange juice or coffee, 2–3 h before operation [16], or of 150 ml of tea, coffee or apple juice 3 h before operation in patients undergoing day-case surgery [17] did not increase the risk of aspiration pneumonitis; unrestricted oral fluids until 3 h before surgery also had no effect in a retrospectively controlled trial [18].

Our study was designed to assess if allowing unrestricted clear fluids until 2 h before anaesthesia would alter the gastric volume and pH, affect anaesthetic complications such as regurgitation or aspiration, and enhance patient comfort.

PATIENTS AND METHODS

The study was a prospective, randomized controlled trial. The investigation was approved by the local Ethics Committee and each patient gave written informed consent.

One hundred patients (ASA grades I–III, > 18 yr) undergoing elective surgery were studied. Patients were excluded if factors known to affect the gastric contents were present—pregnancy, gastrointestinal disease and the ingestion of alcohol, opioids, anticholinergics, histamine type-2 receptor antagonists or metoclopramide in the 24 h before surgery. Patients were allocated randomly, on alternate weeks, to either the control or the study group and received either no premedication or temazepam 10–20 mg with water 30 ml 2 h before operation, at the discretion of the anaesthetist in charge of the case.

TABLE I. *Patient characteristics (number, or mean (range or SD))*

	Study group ($n = 50$)	Control group ($n = 50$)
Age (yr)	64 (21–88)	55 (20–86)
Sex (M:F)	34:16	40:10
Height (cm)	169 (11)	169 (10)
Weight (kg)	72 (15)	73 (14)
ASA (I:II:III)	18:30:2	29:19:2
Operation (major:intermediate)	18:32	23:27
Premedication	35	22

TABLE II. *Fasting duration and volume of fluid ingested in 6 h before surgery (mean (SD))*

	Study group	Control group
Solids fast (h)	14.8 (8.9)	14.6 (8.9)
Fluid fast (h)	2.2 (0.7)	12.9 (9.0)
Fluid intake (ml)	388 (238)	13 (15)

Patients in the control group were fasted from midnight for a morning list and from 06:30 for an afternoon list. Patients in the study group were allowed unrestricted clear fluids (alcoholic drinks and those containing milk or sugar were not allowed), until 2 h before surgery was expected to begin, a time marked by the administration of the premedication if prescribed. The volume of fluid consumed and the time at which the "nil by mouth" order was implemented were recorded on the ward fluid balance chart by the nursing staff. No changes were made to theatre schedules in order to accommodate the varying fasting intervals.

The following data were recorded for each patient: age, sex, height, weight, ASA grade, smoking habit, fasting duration, volume of fluid ingested in the 6 h before surgery and the occurrence of complications possibly attributable to recent ingestion of fluid. Patients were asked to grade the degree of thirst and hunger as nil, mild, moderate or severe immediately before induction of anaesthesia.

Anaesthesia was administered according to the surgical requirements and the preference of the anaesthetist in charge of the case. Immediately after induction, an 18-French gauge Salem sump tube (Argyle) was passed orally into the stomach and correct positioning confirmed either by aspiration of gastric contents or, if none was obtained, by auscultation of 2 ml of insufflated air. Aspiration was performed by an assistant who was unaware of the duration of the patient's fluid fast. All aspiration was performed with the patient supine, in three different tube positions with the stomach being massaged to assist complete emptying. The volume of fluid and pH were measured as soon as possible after collection. The pH was measured with a radiometer (Corning 150), calibrated to two points, 4.0 and 7.0.

Throughout the study, comparison of the groups was made after every 10 patients, to ensure that the study group was not at an increased risk of Mendelson's syndrome.

RGV and pH were compared using the two-sample Student's t test. Proportions were compared using the standard error of the difference between two proportions method. Results are presented as confidence intervals for the difference, with probability levels. Thirst and hunger were compared using the chi-square test.

RESULTS

Patient characteristics were similar in both groups (table I). The groups were comparable also with respect to ASA grade, smoking history and surgical procedure. Major procedures included cholecystectomy, transurethral resection of the prostate and bowel resection. Intermediate procedures included varicose vein surgery, inguinal hernia repair and cystodiathermy. Premedication was prescribed more often in the study group.

No patient was permitted solid food for 6 h before operation; in both groups, the duration of this fast was usually considerably longer (table II). As expected, the duration of the nil-by-mouth period varied less in the study group (1–4 h) than in the control group (6–23 h).

In the study group, the fluid intake in the 6 h before surgery ranged from 50 to 1200 ml. Fluid was ingested by the control group for the purposes of taking oral premedication only. RGV and pH were similar in both groups (table III). The number of patients considered to be at risk of Mendelson's syndrome (those with RGV greater than 0.4 ml kg^{-1} with pH less than 2.5 [19]) was the same in both groups.

Ingested fluid volume did not correlate with RGV or pH. The gastric pH of patients drinking until 2 h before operation was greater than in those who had fasted, but this was not statistically significant.

Patients in the study group experienced less thirst than those in the control group (table IV).

No patient regurgitated or aspirated.

DISCUSSION

Our study has shown that allowing elective surgical patients to drink until 2 h before surgery decreases thirst without prejudicing safety. The ingestion of

Severe	2	23	7	15
	$P < 0.001$		$P = 0.09$	

free clear fluids until the time of oral premedication does not affect either the volume or pH of gastric contents. If the risk of regurgitation is related to the RGV, it is unaltered by preoperative drinking. Should regurgitation occur, patients who have been drinking are at no greater risk of Mendelson's syndrome than those who have fasted. The gastric pH in the study group tended to be greater, and greater than 2.5 more often, than in the control group, although this difference was not significant. This finding may reflect the dilution of gastric acid by the ingested fluids.

In practice, the period of preoperative fast is often prolonged and the mean fasting period of around 13 h in our control group is not atypical. Indeed, the inevitable constraints of conventional fasting, together with alterations in theatre schedules imply that there is a wide variability in the fasting period. Patients find the ensuing hunger and thirst unpleasant, and if antisialagogue premedication had been used this may be even more pronounced than in our control group. In the study group, thirst was a less common and less severe complaint.

Measurement of gastric volume using an aspiration technique may be criticized as underestimating the RGV, but when a multi-orifice sump tube is used the method has been shown to be valid [20]. In any event, any sampling error should be small and consistent between groups.

Temazepam has no effect on gastric emptying or pH [21]. Temazepam was prescribed more often in the study group than in the control group. It is possible that control group patients may have been more anxious, resulting in delayed gastric emptying compared with study group patients. Nevertheless, the RGV was the same in both groups.

We excluded patients with factors likely to delay gastric emptying, such as pregnancy, trauma, opioid administration, and when mechanical or neurological factors such as pyloric stenosis, vagotomy or autonomic neuropathy existed. Our findings cannot be extrapolated to such patients.

Further studies are needed to evaluate the effect of preoperative drinking in patients prescribed opioid–anticholingeric premedication. Similarly, the relevance of our findings in day-case patients should be investigated. Nausea and vomiting are known to be related to the duration of the preoperative fasting period [6]. These aspects were not examined in our study, but investigation of the effect of preoperative drinking on patient recovery is warranted.

In the U.K., patients are scheduled to fast for 4–6 h before induction of anaesthesia, although recent guidelines from the Canadian Anaesthetists' Society have reduced the fluid fast period to 3 h [22]. Our findings support this shorter fluid fast on the basis that patient comfort is increased and safety is not compromised.

ACKNOWLEDGEMENTS

We thank Dr M. Bland, Senior Lecturer in Medical Statistics, St George's Hospital Medical School and Mr D. Simms, Top-Grade Biochemist, Kingston Hospital for the gastric pH estimations.

PAIN RELIEF FOR INFANTS UNDERGOING ABDOMINAL SURGERY: COMPARISON OF INFUSIONS OF I.V. MORPHINE AND EXTRADURAL BUPIVACAINE

A. R. WOLF AND D. HUGHES

SUMMARY

We have undertaken a prospective, randomized double-blind study to compare extradural bupivacaine infusions with i.v. morphine infusions for postoperative analgesia in 32 infants younger than 4 yr undergoing abdominal surgery. "Sham" extradural or i.v. catheters were used to maintain the blinded nature of the study. Both techniques provided adequate analgesia for most of the 36-h postoperative period; differences in the pattern or quality of the analgesia were not detected. Patients in the i.v. morphine group were significantly more sedated; this was accompanied by slower ventilatory frequencies (26.7 (SD 1.8) b.p.m.) compared with the extradural group (33.6 (1.3) b.p.m.). Similarly, oxygen saturation was significantly less ($P < 0.01$) in patients receiving morphine (medians and quartiles of 94.0 (93–96)% compared with 96.0 (93–96)%). Mean systolic arterial pressure was similar in the two groups and there were no life-threatening complications. The lack of sedation was troublesome in three patients in the extradural group. (Br. J. Anaesth. 1993; **70**: 10–16)

KEY WORDS

Anaesthetics local, bupivacaine. Analgesia: postoperative, paediatric. Analgesics: morphine infusion. Anaesthetic techniques: extradural infusion.

The current debate on management of pain in neonates [1] has encouraged renewed interest in the use of regional analgesia for infants undergoing surgery. Extradural anaesthesia with bupivacaine has been shown to modify the haemodynamic [2], hormonal [3] and metabolic [4] responses to surgery in children, and provides effective postoperative analgesia [5]. However, insertion of a lumbar or thoracic extradural block in a small infant requires a high level of technical expertise, and identification of the extradural space becomes progressively more difficult with decreasing age of the subject [2]. A technique of inserting an extradural catheter up to a thoracic level via the easier caudal route has been used in neonates and infants to provide local anaesthesia during upper abdominal surgery [6]. A similar technique with extradural morphine has been described for postoperative analgesia [7].

Variable rate i.v. opioid infusions are used even in young infants for postoperative analgesia, but may have serious side effects such as impaired consciousness or ventilatory depression [8]. Extradural infusions of bupivacaine offer an alternative which avoids opioids, but also has the potential to produce hypotension and complications from extensive local block [9] or systemic absorption of local anaesthetic [10]. We are not aware of any study in this age group comparing analgesia, recovery and side effects of these two techniques. We therefore designed a randomized double-blinded study to evaluate the use of i.v. morphine infusions and extradural infusions of bupivacaine after abdominal surgery in infants and small children.

PATIENTS AND METHODS

After obtaining approval by the local Ethics Committee and informed parental consent, we studied 32 healthy patients (ASA status I and II) aged less than 4 yr undergoing elective abdominal, renal or bladder surgery. Infants older than 4 months received oral trimeprazine 1.5 mg kg^{-1} and topical EMLA (eutectic mixture of local anaesthetic) 90 min before the estimated time of surgery, while those younger than 4 months were not premedicated. Thiopentone and alcuronium were given i.v. at induction of anaesthesia. After tracheal intubation, the lungs were ventilated to normocapnia with 70% nitrous oxide and enflurane up to 1% in oxygen. During operation, an infusion of 5% glucose and 0.225% sodium chloride was given for fluid maintenance, and other fluid losses were replaced with Hartmann's solution, blood or blood products. In addition to this standardized general anaesthetic, patients were allocated randomly to receive either i.v. morphine or extradural bupivacaine during and after surgery. The 16 patients assigned to the i.v. morphine group had a second i.v. cannula inserted before the start of surgery, specifically for the morphine infusion. After a loading dose of morphine 0.15 mg kg^{-1}, an infusion of morphine in 50 ml of 0.9% saline was started. Solutions were made at different concentrations to take into account the increased sensitivity of younger

*Present address, for correspondence: Department of Anaesthesia, Royal Hospital for Sick Children, Yorkhill, Glasgow G3 8SJ.

children to opioids: a 50-μg ml^{-1} solution for children weighing less than 10 kg and a 100-μg ml^{-1} solution for those heavier than 10 kg. Initial infusion rates were 0.1 ml kg^{-1} h^{-1} (5 μg kg^{-1} h^{-1} for < 10 kg and 10 μg kg^{-1} h^{-1} for > 10 kg) and corresponded to the usual starting dosage for morphine infusions in infants at the Bristol Royal Hospital for Sick Children. The 16 patients allocated to the extradural group were turned on their left side before starting surgery, and under sterile conditions an 18- or 19-gauge Tuohy needle from a Portex minipack system 1 (Ref: 100/391/118 or 100/391/019) was inserted through the sacrococcygeal hiatus. After the absence of blood or CSF was confirmed, the catheter (0.9 mm or 0.63 mm o.d.) was inserted rostrally to a distance calculated to leave the tip between the first and second lumbar vertebrae. An initial dose of 0.25% plain bupivacaine was injected according to the formula by Takasaki [11] relating the volumes of injectate to the required number of spinal segments to be blocked (0.05 ml kg^{-1} per segment). An infusion of 0.25% bupivacaine was commenced immediately after the initial dose and infused throughout surgery at a rate of 0.1 ml kg^{-1} h^{-1}. Intraoperative heart rate and arterial pressure were measured at 5-min intervals and were maintained within 20% of the preoperative values using additional doses of either morphine 40 μg kg^{-1} or 0.25% bupivacaine up to a maximum of 1 ml kg^{-1}, depending on the group.

After surgery, patients were taken to a recovery area where the route of analgesia was disguised to prevent observer bias on pain observations. The analgesic solution (containing either morphine or bupivacaine) passed from the syringe pump labelled with the trial number to a bacterial filter wrapped in gauze and strapped to the chest. Two tubes emerged from the gauze wrapping. In the morphine group, the bacterial filter was connected to the i.v. cannula via covered infusion tubing, while a "sham" extradural cannula was strapped down the back to make it indistinguishable from a true extradural. In the extradural group, the bacterial filter was connected to the extradural cannula, while a sham i.v. infusion catheter and cannula were strapped to the arm under opaque tape to make them indistinguishable, by direct observation, from an i.v. cannula. Additional doses of i.v. morphine or extradural bupivacaine were given as necessary by one of the investigators to ensure that all patients were free from pain before returning to the ward and commencing pain observations.

On arrival of the patient in the ward, arterial pressure, oxygen saturation and ventilatory frequency were recorded. Sedation and analgesia were assessed after 1 h by a trained nurse observer who was unaware of the type of analgesia given. Further assessments were made hourly for the first 6 h, then 3-hourly up to 30 h and finally at 36 h according to observed behaviour during the preceding period. Sedation was assessed with a four-point scale: 0 = appropriately asleep; 1 = awake and alert; 2 = drowsy but responds to stimulation; 3 = very sedated. Pain measurement was based on a scoring system described by Hannallah and colleagues [12], which obtains a summed value of between 0 and 10 from observations of arterial pressure, crying, movement, agitation and localization of pain. If pain scores increased to greater than 4, the nursing staff were permitted to increase the infusion rate incrementally by 1 ml h^{-1} after informing one of the investigators. The maximum infusion rate permitted was 4 ml h^{-1}. The nurse observers were instructed to decrease the infusion rate and inform one of the investigators if systolic arterial pressure decreased to less than 20% of the baseline value, if ventilatory frequency decreased to less than 15 b.p.m. or if the patient became sedated or difficult to rouse (sedation score 3). Infusion rates could also be reduced incrementally according to usual ward practice if patients appeared to have little or no pain. Other recordings included major side effects or complications and the time to first bowel action after surgery. Oxygen saturation was monitored continuously during the infusions and set to alarm at oxygen saturations less than 85%. If parenteral analgesia was still required after 36 h, the patient continued with the same method of pain relief but in an unblinded fashion. Paracetamol was not prescribed routinely in the first 36 h, but could be given if the patient became pyrexial. While the nurse observers remained "blinded", it was necessary for the anaesthetic team to be aware of which infusion was being used. Any procedure that could result in unblinding the trial was carried out by another member of the ward staff or an anaesthetist. This included daily inspections of the i.v. and extradural sites to ensure that they remained clean and were functioning normally, but every effort was made to limit the interaction between the anaesthesia team and the nurse observers.

Statistical significance for parametric data was determined using analysis of variance and Student's *t* test. Ordinal data and nominal data were analysed by the Mann–Whitney *U* test and chi-square analysis with Yates' correction.

RESULTS

The ages, weights and duration of the surgical procedure did not differ significantly between the groups (table I).

Pain scores were categorized into three groups

TABLE I. *Patient data and duration of surgery (median (range)), with operation type by group allocation*

	Extradural group	Morphine group
Age (months)	9 (3–46)	14 (3–42)
Weight (kg)	9.8 (6.0–16.0)	11 (5.2–21.4)
Duration of op. (min)	125 (100–210)	120 (80–340)
Operation		
Reimplantation of ureters	7	3
Nephrectomy	5	4
Partial nephrectomy	1	2
Bladder surgery	1	1
Pyeloplasty	1	3
Pyelolithotomy	—	2
Laparotomy	1	—
Body wall sarcoma	—	1

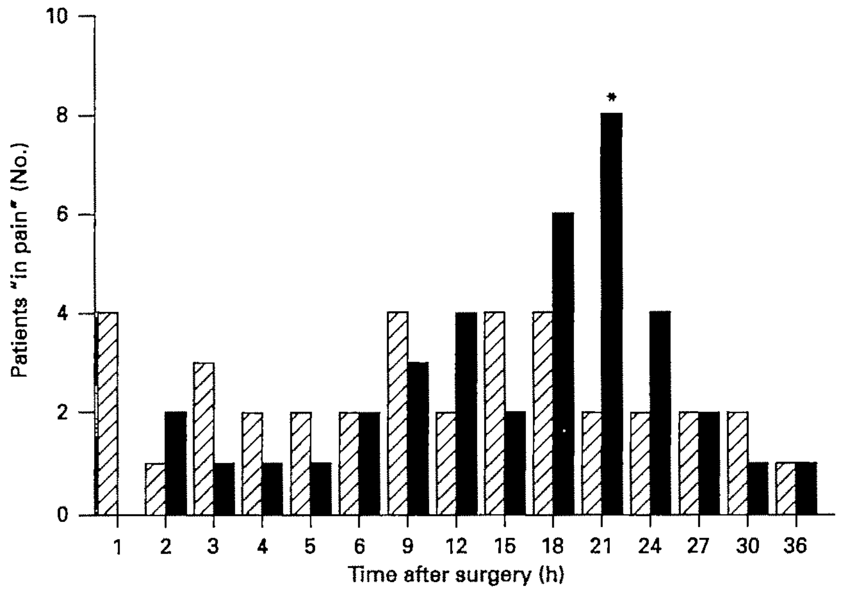

FIG. 1. Comparison of the numbers of patients in the extradural bupivacaine (▨) and morphine (■) groups with pain scores of 4 or more ("in pain") over the 36-h study period. *$P < 0.05$.

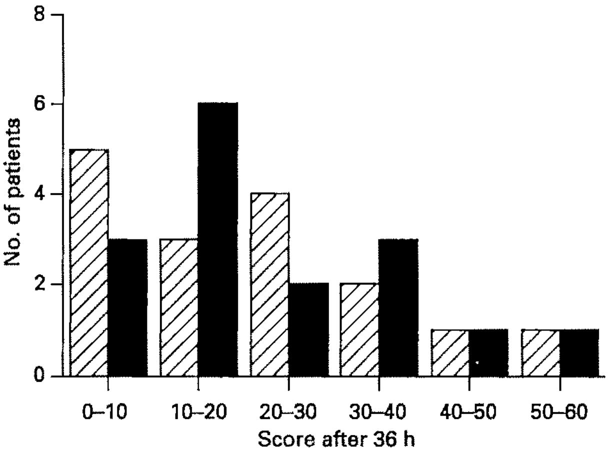

FIG. 2. Distribution of the total pain scores accumulated over 36 h (cumulative pain score) by each patient for the extradural bupivacaine (▨) and morphine (■) groups. Cumulative pain scores are displayed in bins of 10 on the X axis and the number of patients in each bin are shown on the Y axis.

according to previous experience with this scoring system: 0–3 = minimal or no pain; 4–6 = mild pain; 6 or greater = moderate to severe pain. The majority of patients were in the "no pain" category during the study, regardless of the designated method of analgesia. Comparison of the numbers of patients judged to have pain (pain score greater than 3) did not show any significant differences between the groups except at the 21-h observation (fig. 1). All patients completed the study and none had to be withdrawn because of failure of analgesia. There was variation in the quality of analgesia between patients which was reflected in the range of cumulative pain scores for each patient (fig. 2), but there was no difference in the distribution of cumulative pain scores between the groups.

Most patients required increases in the infusion rates from the baseline settings: extradural infusion rates varied from 0.1 to 0.4 ml kg^{-1} h^{-1}, while morphine delivery varied from 10 to 40 μg kg^{-1} h^{-1}. In both groups, the mean infusion rates increased to a maximum at 15 h and then declined. Increasing the infusion rates for those patients in pain appeared to control analgesia, although pain scores did not always decrease in the first 1 h after the increase. Further stepwise increases in infusion rate were often needed before pain was controlled. No patient required reduction of infusion rates because of hypotension or ventilatory depression. One patient in the extradural group was inadvertently given paracetamol for pain, and another three patients in each group were given paracetamol during the study because of pyrexia.

Patients in the bupivacaine group were less sedated than those in the morphine group (fig. 3).

Significant differences were observed during the first 1 h after operation and again at 27 and 30 h. The lack of sedation became troublesome in three of the patients having extradural infusions. The nurse observers noted agitation, fidgeting and restlessness as side effects in these patients. Although these patients could be settled without changing infusion rates, they needed regular attention to stop them from interfering with dressings and drains. It had been expected that sedation might interact with observed pain scores such that sedated patients would have lower pain scores than unsedated ones. However, while patients who were appropriately asleep (sedation 0) usually had a pain score of 3 or less for that observation period (96.6% in the extradural group and 98.2% in the morphine group), overall comparison of sedation scores and pain scores did not show a correlation in either of the groups.

Observed ventilatory frequencies were significantly less in the morphine group (fig. 4), and this was reflected in reduced oxygen saturation in the early postoperative period (fig. 5). Mean ventilatory frequencies over the 36-h study, calculated from an averaged value for each individual, were 33.6 (SD 1.3) b.p.m. in the extradural group and 26.7 (1.8) b.p.m in the morphine group. Median oxygen

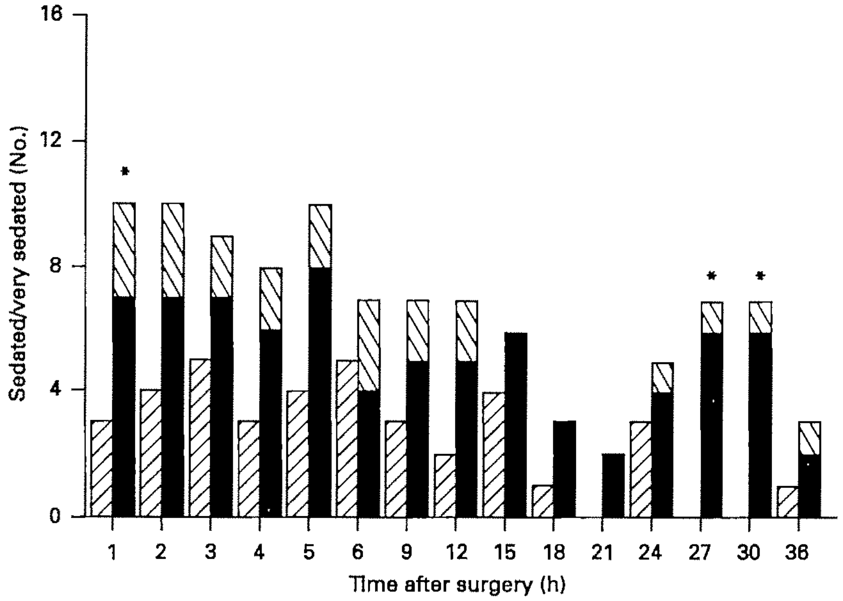

FIG. 3. Comparison of the numbers of patients in the extradural and morphine groups observed as sedated (sedation score 2) or very sedated (sedation score 3) over the first 36 h after operation. ▨ = Bupivacaine group with sedation score 2; ■ = morphine group with sedation score 2; ▧ = morphine group with sedation score 3. $^{*}P < 0.05$.

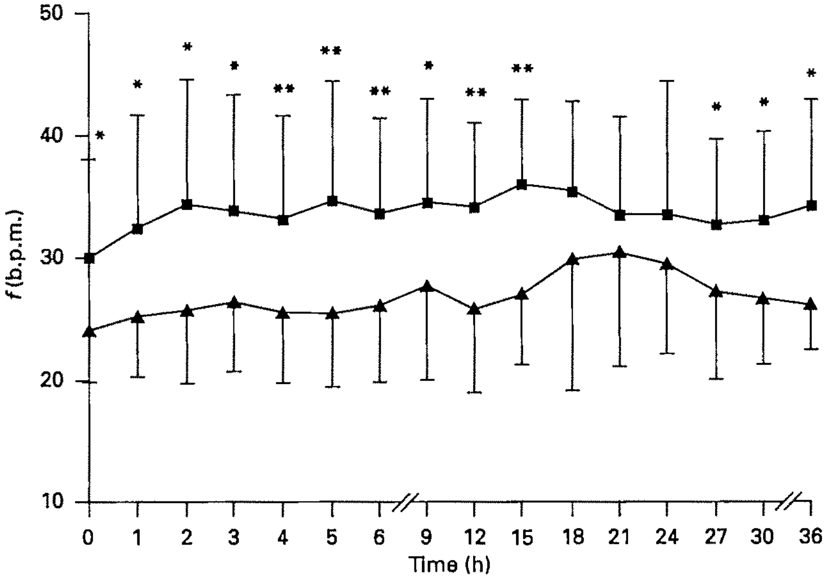

FIG. 4. Ventilatory frequencies (*f*) for patients receiving extradural bupivacaine (■) or morphine (▲) analgesia (mean, SD). $^{*}P < 0.05$; $^{**}P < 0.01$.

saturations and quartiles were 96 (95.2–97) % in the bupivacaine group and 94 (94–94.7) % in the morphine group.

The decreased ventilatory frequencies and oxygenation did not appear to have any clinical consequences in this study and, although the oxygen saturation monitor alarmed occasionally because of disconnection, there were no episodes of major ventilatory depression or apnoea causing desaturation to less than 85 %.

One patient in the extradural group had a dural tap at the time of insertion of the Tuohy needle. After removing the needle, the procedure was repeated without a problem and the caudal catheter inserted. CSF could not be aspirated through the threaded catheter and the patient remained in the study without further complication. The averaged systolic arterial pressure for each patient was significantly less ($P < 0.01$) in the bupivacaine group (97.4 (SD 2.7) mm Hg) than in the morphine group (101.1 (3.6) mm Hg) during surgery, but this difference did not continue in the postoperative period. Mean systolic arterial pressures during the postoperative period were 109.3 (3.7) mm Hg for the extradural group and 110.3 (5.3) mm Hg for the morphine group, and there were no individual problems with hypotension. None of the patients in either group had distressing or persistent vomiting. There was wide variability in the time to first bowel action after surgery, but no difference between treatment groups could be detected: 62.9 (44.8) h for the extradural group and 65.6 (36.3) h in the morphine group. No other major complications or side effects were noted by the nursing staff, except for the comments on

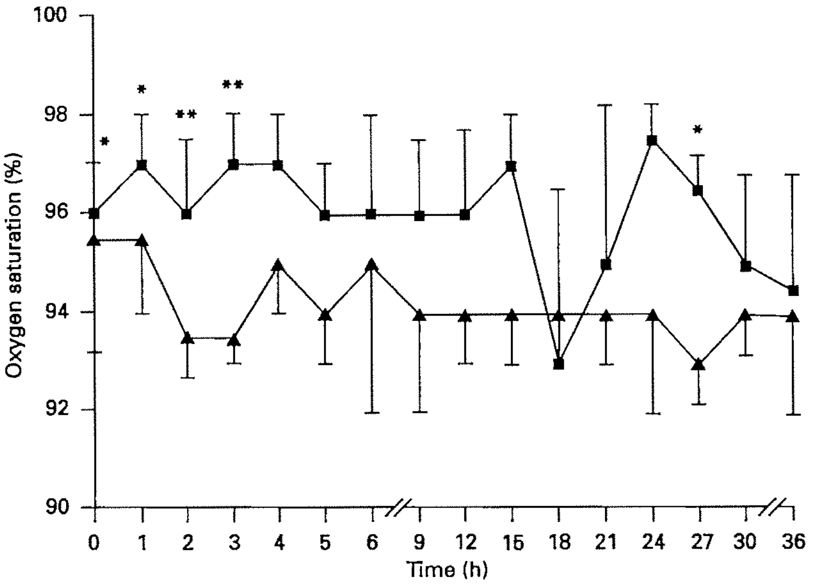

FIG. 5. Oxygen saturation for patients receiving extradural bupivacaine (■) or morphine (▲) analgesia (median, quartiles). $*P < 0.05$; $**P < 0.01$.

restlessness discussed above. The incidence of urinary retention could not be evaluated because 30 of the patients had indwelling urinary catheters.

DISCUSSION

Postoperative analgesia with nurse-administered i.m. opioids still remains the most common method of pain relief after surgery [13], despite the availability of more effective techniques. I.v. morphine infusions have been used in children for some years [8, 14] and are feasible even in infants younger than 6 months [15]. However, the technique is not used commonly outside an intensive care unit in younger age groups because of the risks of ventilatory depression and the requirements for close monitoring. Infusions of extradural bupivacaine [2, 5] can also provide postoperative analgesia in children, but have never been compared with morphine.

A prospective double-blind study comparing extradural bupivacaine with i.v. morphine would not be possible in adults because of the obvious changes in sensation from the local anaesthesia. However, it was achieved in a younger age group because of their limited verbal communication, the lack of motor block from a 0.25 % bupivacaine infusion [2], and by elaborately disguising the technique. In this study, most patients had good analgesia, irrespective of the method used. The distributions of pain scores with time (fig. 1) or by patient (fig. 2) were similar. While the null hypothesis cannot be proven from this study of 32 patients, the results show no major clinical difference in analgesia between the two techniques. It could be argued that the pain scoring system was not sensitive enough to discern differences between the two groups. However, significant differences in pain scores have been recorded in previous studies on the same ward using identical methods [16, 17]. There was no correlation between levels of sedation and pain scores in this study, which was surprising. The unsedated patient can become agitated and rate high pain scores without being in pain. Analgesic techniques, such as i.v. morphine, that produce sedation in addition to pain relief may appear more effective than a non-sedating technique such as extradural bupivacaine because of the reduction in conscious level.

The difference in sedation scores between the two groups was marked. Infants in the extradural group were active much of the time and this was beneficial from the aspect of nursing supervision for ventilatory depression. However, while the lack of sedation made little difference in the infants younger than 6 months, it was more noticeable and occasionally troublesome in the older children (three patients). Overactivity and restlessness have not been reported previously as side effects of extradural analgesia, although they should be expected, particularly in the older and more mobile infants who have little or no pain. This can become a problem for the nursing staff in a busy ward if a child needs supervision to stop it investigating newly placed dressings and drains. Sedation with morphine or diazepam may occasionally be required, to supplement an extradural technique.

The reduced ventilatory frequency and oxygen saturation in those patients receiving morphine were not clinically obvious or important in this study, but may be relevant in the choice of postoperative analgesia for infants with immature ventilatory drive or pre-existing lung disease. Local techniques can eliminate the need for centrally acting drugs that depress ventilation and, used in place of general anaesthesia, may reduce postoperative apnoea in the "at risk" patient [18, 19]. Resting ventilation is reduced after extradural analgesia, but the ventilatory response to carbon dioxide is enhanced [20] and this may be protective, particularly in the early postoperative period. Extradural bupivacaine may, therefore, be a desirable alternative to opioid analgesia in the infant with ventilatory impairment.

The dose of morphine required to achieve analgesia in this study varied from 5 to 40 $\mu g\ kg^{-1}\ h^{-1}$ and was similar to established treatment regimens for this age group [14]. The initial infusion rate of 5–10 $\mu g\ kg^{-1}\ h^{-1}$ was adequate in the early postoperative period, but required adjustment as the effects of general anaesthesia and the initial loading dose of morphine decreased. Greater initial rates of infusion of i.v. morphine might have improved analgesia after 12 h, but would have increased sedation and ventilatory depression in the early postoperative period. In both groups, alteration of the infusion rates achieved pain control, but there was an inevitable lag between increasing the infusion rates and reduction in pain scores. Single additional doses of i.v. morphine or extradural morphine would have produced more immediate analgesia, but were not possible within the blinded study design.

Desparmet and colleagues [5] have used infusions of 0.25% bupivacaine via a lumbar extradural catheter in children undergoing urogenital or lower limb surgery and reported adequate analgesia with an infusion rate of 0.08 $ml\ kg^{-1}\ h^{-1}$. In our study, an initial infusion rate of bupivacaine 0.1 $ml\ kg^{-1}\ h^{-1}$ had to be increased in all but three patients to maintain adequate analgesia; a starting infusion rate of 0.15 $ml\ kg^{-1}\ h^{-1}$ might have been more appropriate. The differences in our results may reflect that our patients were younger, that they underwent abdominal surgery and that a different technique was used for catheter insertion. Unlike local anaesthetic extradural infusions in adults [21], bupivacaine infusions in infants produce stable levels of analgesia [5] and can produce an ascending block [9]. Periodic pinch tests should be undertaken to ensure that the block is not extending to too high a level. Infusions of extradural bupivacaine also have the potential to cause toxicity from systemic accumulation, but the risk appears to be low when appropriate infusion schemes are used [5].

Cannulation of the extradural space by the caudal route is technically less difficult than the lumbar route in small infants, but the risk of contamination and potential for infection may be greater because of close proximity to the perineum. A lumbar approach is generally preferable, but the choice of route depends on the size of the infant and expertise of the anaesthetist. In this study, all catheters were taped away from the perineum with waterproof dressings and removed within 3 days of insertion. We are not aware of any reported cases of infection caused by indwelling caudal catheters, but published experience with this technique remains limited. Long-term use of caudal catheters would be contraindicated unless they were tunnelled s.c.

Extradural morphine is used for postoperative analgesia in children, but can cause sudden and late onset and sometimes sudden ventilatory depression [22, 23]. Combining opioids and local anaesthetics in an extradural mixture may lessen the risks by reducing individual doses of the drugs and their side effects [16, 17], but younger infants still require intensive monitoring. Extradural infusions of bupivacaine, combined if necessary with small incremental doses of i.v. morphine for additional analgesia and sedation, may be more appropriate in these patients and help avoid the need for a stay in the intensive care unit. Our current clinical practice is to give infants older than 6 months undergoing abdominal surgery an intraoperative dose of i.v. morphine 0.05–0.1 $mg\ kg^{-1}$ or fentanyl 0.5–2 $\mu g\ kg^{-1}$ in addition to extradural analgesia with 0.25% bupivacaine. The analgesia and sedation from the single dose of opioid helps to prevent restlessness in the early postoperative period.

In conclusion, extradural analgesia with bupivacaine given via a caudal catheter provided excellent postoperative analgesia in infants after abdominal surgery. It may be preferable to a morphine infusion in neonates and younger infants who are particularly sensitive to ventilatory depression and in whom sedation is neither necessary or desirable. Older children may require additional sedation or analgesia with this techniques to prevent restlessness in the postoperative period.

EXTRA INSPIRATORY WORK OF BREATHING IMPOSED BY CRICOTHYROTOMY DEVICES†

R. OOI, W. J. FAWCETT, N. SONI AND B. RILEY

SUMMARY

Using a lung model for spontaneous ventilation, we have assessed the additional work of inspiration imposed by a variety of cannulae ranging from the 12- and 14-gauge intravascular cannulae to the 8.0-mm i.d. adult tracheostomy tube. Work (W) ranged between 9 and 2262 mJ litre^{-1} and power ($\dot{W}$) between 0.2 and 37.7 mW litre^{-1} min; the smallest values were obtained with the 8.0-mm i.d. adult tracheostomy tube and the 12- and 14-gauge intravascular cannulae gave the largest values. With any given cannula, W and $\dot{W}$ were influenced by ventilation (tidal volume and frequency) and ventilatory wave pattern of the analogue lung. The results obtained from the 12- and 14-gauge cannulae represent what is probably an excessive inspiratory workload, whereas the other four devices (Portex MiniTrach, 4.0, 6.0 and 8.0 tracheostomy tubes) may be suitable in the short term for relieving airway obstruction and compatible with spontaneous ventilation. (Br. J. Anaesth. 1993; **70**: 17–21)

KEY WORDS

Equipment: tracheostomy tubes. Ventilation: inspiratory work.

Percutaneous cricothyrotomy is an important technique in the emergency management of upper airway obstruction. A wide range of cannulae have been considered as suitable for this procedure under emergency conditions. Generally, oxygen at positive pressure is administered either by intermittent positive insufflation or by jet ventilation. It is conceivable that, under some circumstances, the facilities to provide this type of positive pressure support may be unavailable and spontaneous ventilation has been advocated. If this is to be successful, the standard resuscitation manuals advocate the insertion of a large-bore cannula of at least 5.0 or 6.0-mm i.d. in adults [1, 2], but this demands more technical expertise.

The aim of the present study was to assess a variety of cannulae that may be available for percutaneous cricothyrotomy. Previous studies of the impact of external resistance on breathing have used continuous gas flows and calculated resistance by measuring driving pressures across the airway [3–5]. However, the results of resistance are difficult to relate to the clinical situation. This study avoided such criticisms by following Mecklenburgh and colleagues [6] and measuring the additional work of inspiration required if spontaneous ventilation is attempted through any of the cannulae.

MATERIALS AND METHODS

The cannulae under study were as follows: 12-gauge Medicut and 14-gauge Abbocath intravascular catheters attached by 3.5-mm tracheal tube connectors, the 4.0-mm i.d. minitracheotomy tube (Portex, MiniTrach) and the 4.0-, 6.0- and 8.0-mm i.d. Portex tracheostomy tubes. Duplicate samples of each device were tested.

Spontaneous ventilation was simulated using a lung model [7]. This was connected to each test cannula in turn. In the first part of the study, a modified Cape–Waine ventilator was used to drive the lung model, simulating a sine-wave respiratory flow pattern, with tidal volume settings of 350 and 500 ml, and with a ventilatory frequency (f) of 10, 16 and 20 "breaths" per minute (b.p.m.). The experimental model is shown in figure 1.

In the second part of the study, a "waveform generator", comprising an interlinked pair of bellows (fig. 2) connected to a Nuffield Oxford ventilator, was used to drive the lung model. The inspiration time, as a fraction of the ventilation period (T_I/T_T) was varied between 0.24 and 0.48 while the tidal volume setting of the ventilator was kept at 350 ml and the frequency setting at 16 b.p.m. The apparatus was used to assess the inspiratory workload of the Portex MiniTrach, 4.0-, 6.0- and 8.0-mm i.d. tracheostomy tubes.

The measurements taken in this study were airway

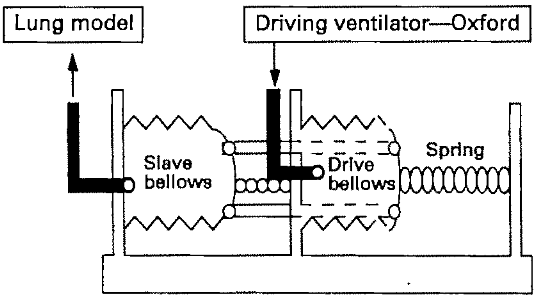

FIG. 2. Waveform generator to inter-link lung model and driving ventilator. Inflation of drive bellows results in negative pressure exerted in the coupled slave bellows, resulting in inspiration.

pressure (P) and ventilatory flow ($\dot{v}$). P was measured immediately proximal to the cannula using a pressure transducer (Scientific Electro Systems, 170 PC) and $\dot{v}$ was measured using a variable orifice pneumotachograph (Accutach, McGaw Respiratory Therapy) attached to a differential pressure transducer (Scientific Electro Systems, 170 PC). The airway pressure transducer was calibrated using a water manometer and the pneumotachograph was calibrated in air using rotating bobbin flowmeters (Gap-meter, A_6 and A_{10}). The pressure and flow signals were digitized at 200 Hz onto a computer chart recorder program.

It is common to speak of the "work of breathing". However, breathing is a continuous process over time. Therefore, strictly, it is appropriate to refer only to the work of one breath or to the power (rate of working) of breathing. The mathematical equation described by Engstrom and Norlander [8] was used to calculate the additional work of one breath:

$$\int_{t_1}^{t_2} P.\dot{v}dt$$

that is, the integral of $P.\dot{v}$ during the inspiratory phase from t_1 to t_2, where P is the instantaneous pressure change across the cannula and $\dot{v}$ the instantaneous flow through it. This additional inspiratory work (W) was expressed in mJ/litre tidal volume. The additional inspiratory power of breathing (J s^{-1} or Watts ($\dot{W}$)) is the inspiratory work of one breath divided by the respiratory period. It is expressed in Watts per litre min^{-1} of total ventilation. These values of work and power were averaged over six successive breaths.

RESULTS

In the first part of the study, when the sine-wave ventilatory pattern was used (tables I, II), W ranged from 9 to 2262 mJ litre^{-1} and $\dot{W}$ from 0.2 to 37.7 mW litre^{-1} min. Peak pressure ($\hat{P}$), W and $\dot{W}$ increased progressively as successively narrower tubes were used, even though tidal volume decreased in the process. $\hat{P}$, W and $\dot{W}$ also increased with frequency and tidal volume.

In the second part of the study, the waveform generator produced a ramp waveform (fig. 3). Again, $\hat{P}$, W and $\dot{W}$ increased as progressively narrower tubes were used (table III), but they decreased as the fraction of the ventilatory cycle assigned to inspiration was increased from 0.24 to 0.48.

In both parts of the study, the results were consistent when the measurements were repeated with the second set of transtracheal devices; the maximum discrepancy was less than 2%.

DISCUSSION

The normal power of breathing has been quoted as 70 mW [9]. For a total ventilation of 5–8 litre min^{-1}, this is 9–14 mW litre^{-1} min. It has also been reported

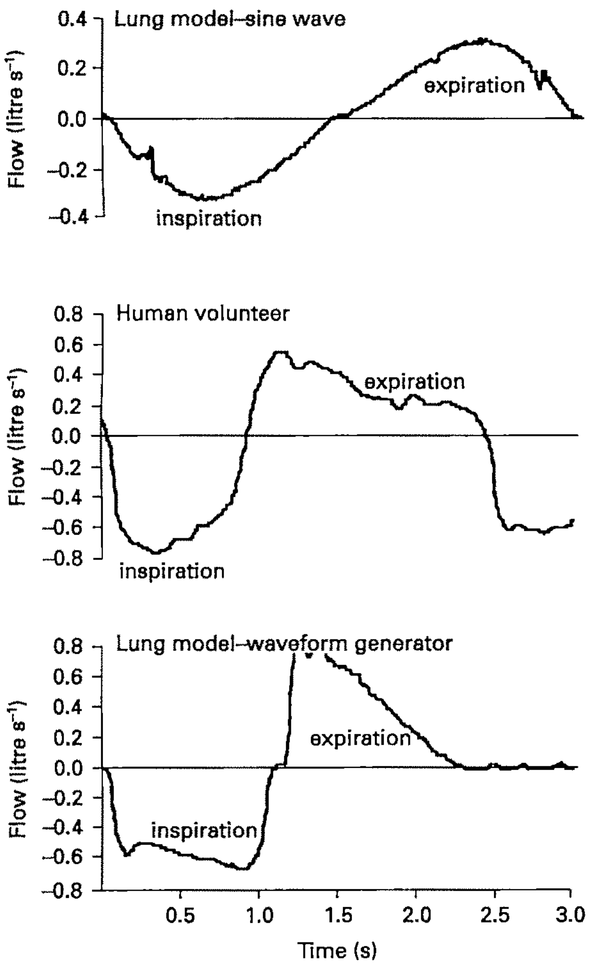

FIG. 3. Ventilatory flow recordings taken from a human subject (breathing through a Mapleson A–Magill system at 6 litre min^{-1}) and from a lung model (using the Cape–Waine and waveform generator attachment).

that few patients can sustain spontaneous ventilation when $\dot{\bar{W}}$ is 300–400% of normal [10]—that is, additional power of 18–42 mW litre^{-1} min. As the 12- and 14-gauge cannulae required an additional 30–40 mW litre^{-1} min, even at a ventilation of only 2.5 litre min^{-1}, they are clearly unsatisfactory for sustained use, although there has been a report of satisfactory use of two 12-gauge cannulae together [11]. In contrast, the wider tubes impose much lighter loads on breathing. The MiniTrach required 3.4–16.7 mW litre^{-1} min (30–190% of normal), for up to 9.4 litre min^{-1} ventilation. This suggests that, although designed primarily for tracheobronchial toilet, this device may provide a satisfactory temporary airway before provision of a definitive airway. For the 4.0- and 6.0-mm i.d. paediatric tracheostomy tubes, the loads range between 20–130% and 3–33% of normal, respectively. For comparison, the adult 8.0-mm i.d. tracheostomy tube imposed 1–10% of normal.

With the sine-wave flow from the Cape–Waine ventilator, the tidal volume decreased as progressively larger loads were applied (tables I, II). Fortuitously, this may reflect how a patient would respond when expected to breathe through these cannulae. This would lead to carbon dioxide retention and hypoxaemia.

As the resistance of the cannulae, and the flows through them, increase, it is to be expected that $\hat{P}$, $\bar{W}$ and $\dot{\bar{W}}$ increase. Tables I–III show that there is a limited range of the ratio $\bar{W}:\hat{P}$. This can be explained theoretically. Thus, if inspiratory flows were constant throughout inspiration, and laminar, and if tidal volume was doubled, the flow and the pressure difference ($\hat{P}$) would also increase by a factor of 2. Work, the integral of flow times pressure, would increase by a factor of 4. Therefore $\bar{W}$ (work per litre of tidal volume) would increase by a factor of 2, and $\bar{W}:\hat{P}$ by a factor of 1: the ratio would be unaltered. If the flows were constant but turbulent, doubling the tidal volume would increase $\hat{P}$ by a factor of 4, and work by a factor of 8. Therefore $\bar{W}$ would increase by a factor of 4; but $\bar{W}:\hat{P}$ would again be unaltered. A similar argument shows that $\bar{W}:\hat{P}$ is

TABLE III. *Effect of altering inspiratory time (T_I/T_T) with the waveform generator (figs 2 and 3) on the inspiratory work (W) and power ($\dot{W}$). also independent of frequency. In the present experiments, $W:\hat{P}$ was consistently less than 1, but flow was not constant. However, it can be shown (see Appendix) that, for sine-wave flow, with a 1:1 I:E ratio (as for tables I and II), $W:\hat{P}$ should be $\pi/4$ (0.78) for laminar flow and 2/3 (0.67) for fully turbulent flow, irrespective of tidal volume and frequency. If allowance is made for the inaccuracies in $W:\hat{P}$ that arise when $\hat{P}$ is small, this suggests that flow was laminar through the 12- and 14-gauge cannulae, but turbulent through the wider tubes.

With the waveform generator, driven by the Nuffield Oxford ventilator, the tidal volume was nearly constant for the range of tubes studied (table III). Here, the reduction in W and $\dot{W}$ as T_I/T_T was increased (at constant frequency) can be attributed to the reduction in peak flow and, hence, in $\hat{P}$.

In conclusion, the 12- and 14-gauge cannulae represent what is probably an excessive inspiratory workload, whereas the other four devices may be suitable in the short-term for relieving airway obstruction. Given the familiarity of anaesthetists in intensive care in inserting the MiniTrach, these findings suggest that this device may have a role in the management of airway obstruction. The 6.0-mm i.d. paediatric tracheostomy tube would provide the least additional work of breathing for a cannula compatible with easy insertion by cricothyrotomy.

APPENDIX

THEORETICAL VALUE FOR $W:\hat{P}$ WITH SINE-WAVE FLOW

For laminar flow through a resistance, $p = k.\dot{v}$ (1)
where p = instantaneous pressure difference across the resistance; $\dot{v}$ = instantaneous flow through it; k = a constant.

Instantaneous power (rate of doing work on the resistance) is given by:

$$\dot{w} = p\dot{v}$$

therefore,

$$\dot{w} = k\dot{v}^2 \tag{2}$$

For sine-wave flow, with an I:E ratio of 1:1,

$$\dot{v} = \hat{\dot{v}}\sin(2\pi ft) \tag{3}$$

where $\hat{\dot{v}}$ = peak flow, f = frequency of the sine-wave (ventilatory frequency), and t = time from start of the inspiratory sine wave.

The work done during inspiration is given by:

$$W_I = \int_0^{1/2f} \dot{w}\,dt \tag{4}$$

Substituting (2) and (3) in (4) gives:

$$W_I = k\hat{\dot{v}}^2 \int_0^{1/2f} \sin^2(2\pi ft)\,dt \tag{5}$$

Expressing the progress of a sine-wave in terms of angle, θ, instead of time t (from the start of the sine-wave) gives:

$$\theta = 2\pi ft \tag{6}$$

whence

$$dt = 2\pi ft\,d\theta/2\pi f \tag{7}$$

also, when $t = 1/2f, \theta = \pi$. (8)

Using (6), (7) and (8) in (5) gives:

$$W_I = (k\hat{\dot{v}}/2\pi f)\int_0^{\pi} \sin^2\theta\,d\theta$$

Using integral 296 from Weast [12], and equation (1), this integrates to:

$$W_I = \hat{P}\hat{\dot{v}}/4f$$

where $\hat{P}$ is the peak pressure difference across the resistance.

However, for a 1:1 sine wave, it can be shown that

$$\hat{\dot{v}} = \pi V_T f,$$

where V_T is the tidal volume. Therefore,

$$W_I = \hat{P}\pi V_T/4,$$

but the work per litre $W = W_I/V_T$. Therefore

$$\frac{W}{\hat{P}} = \frac{\pi}{4} = 0.78$$

For fully turbulent flow through the resistance,

$$p = k\dot{v}^2$$

A parallel analysis, using integral 297 from Weast [12], leads to

$$\frac{W}{\hat{P}} = \frac{2}{3} = 0.67$$

EVIDENCE FOR DYNAMIC PHENOMENA IN RESIDUAL TRACHEAL TUBE BIOFILM

T. J. J. INGLIS

SUMMARY

It has been proposed recently that a dynamic physical process occurring in the tracheal tube might account for the dissemination of bacteria and biofilm fragments into the lungs during mechanical ventilation, and the subsequent development of ventilator-associated pneumonia. In this study of tracheal tubes from consecutive adult intensive care patients, biofilms were detected radiographically in 45 of 50 tubes, and were found at the lower end of the tube more often than at the upper end ($P < 0.005$). In 37 of 50 tracheal tubes, the maximum biofilm thickness was equal to or greater than the 0.5 mm required for gas–liquid interaction in a tube with an i.d. of 8.5 mm. In 23 of 50 tubes, wave-like patterns were found. Five tubes had no biofilm inside the bevelled tip and another six showed evidence of biofilm loss for a greater distance from the tip. These observations suggest that the distribution of tracheal tube biofilm is caused at least in part by dynamic phenomena in the tracheal tube. (Br. J. Anaesth. 1993; **70**: 22–24)

KEY WORDS

Bacteria: biofilm deposition. Equipment: tracheal tube. Intensive care.

The "biofilm" or fluid layer lining found in tracheal tubes after several hours of use has been implicated as a potential source of bacteria that subsequently colonize the mechanically ventilated lung [1]. Dissemination from the fluid lining layer during ventilator gas flow has been demonstrated *in vitro*, and evidence presented in support of bacterial dissemination from the tracheal tube *in vivo* [2]. More recently, simulation experiments with adult tracheal tubes have led to the proposal that gas–liquid interaction inside the tube might result in dissemination of contaminated fluid particles into the ventilated lung [3].

This phenomenon was explored further by radiographic examination of the distribution of residual luminal biofilm in a series of tracheal tubes.

MATERIALS AND METHODS

Tracheal tubes were collected from consecutive adult patients in a general medical–surgical Intensive Care Unit, and kept in a horizontal position at 4 °C before transit and storage at −20 °C. Refrigeration lasted 1–18 h and transit 5–15 min. The above approach was taken in order to minimize any redistribution of luminal biofilm, and to prevent any deterioration caused by bacterial growth. The outer surface of each tube was cleaned with cotton wool and ethyl alcohol, and each end was sealed with parafilm immediately before storage at −20 °C. After removal from −20 °C storage, each tube was allowed to thaw until the biofilm surface was moist, whereupon approximately 5 g of zinc metal powder (BDH, Poole, Dorset) was tipped into the tube, to excess. The tube was occluded at both ends, upended twice and rotated gently around its longitudinal axis to ensure that the fine powder had covered the entire luminal surface of the tube. Non-adhering powder was removed by gently tapping the lower end of the tube on a flat horizontal surface. Each tube was then wrapped in damp blotting paper and placed in a self-seal polythene bag to prevent further drying.

Tracheal tubes were radiographed immediately in two longitudinal views at 90° to each other, using a decreasing load generator at 50 kV and 2.5 mA (M100, Phillips Medical Systems, Leeds), a Quanta Detail screen set for fine focus (FFD 100, Dupont, Stevenage) and Chronex 7 radiographic film (Dupont).

Radiographs were viewed against a single coldlight viewing box on one occasion, and biofilm thickness measured with micrometer dialgauge callipers (Camlab, Cambridge). Biofilm distribution was measured against a Magill curve template (fig. 1), and recorded when a black negative image was observed between the tracheal tube wall and the luminal zinc coating.

RESULTS

A residual biofilm was present in all but five of the 50 tracheal tubes examined radiographically. Biofilm distribution was complex; nevertheless, some common features were apparent. The proportion of

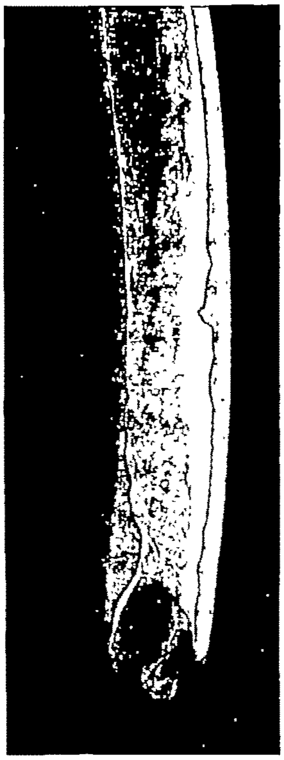

FIG. 4. Wave-like formation in luminal biofilm.

tubes with detectable biofilm decreased progressively from section A near the tip to section D (table I) ($P < 0.005$). In 49 of 50 cases, the duration of tracheal tube was known. The pattern of biofilm distribution was not significantly affected by increased duration of intubation (fig. 2).

Fewer tubes had a biofilm in the region of the bevelled tip than in the adjacent section A. Quantitative analysis of the tip region revealed three different patterns of zinc distribution: present on the inside surface of the bevelled tip (35); absent from only the inside of the bevel (five) (fig. 3A); absent for a greater distance past the bevel (six) (fig. 3B). There was no relationship apparent between these patterns of distribution and duration of intubation.

The maximum thickness of residual biofilm observed was > 0.5 mm in 37 (74%) tracheal tubes. Again, no correlation was found with duration of use.

One or more biofilm crests, similar to waves, were observed in the residual biofilm in 23 (46%) tubes (fig. 4). The proportion of tracheal tubes in which this biofilm formation was observed increased with duration of use, but the relationship was not statistically significant (table II).

DISCUSSION

The tracheal tube has undergone several improvements since it was first introduced, including those designed to reduce tracheal and laryngeal trauma. Less attention has been paid to the design aspects of its principal function as a tubular conduit for inspiratory and expiratory gas flow.

Two decades ago, Clarke and co-workers considered the flow of gas along a narrow bore tube with a viscoelastic fluid lining layer [4]. Their findings indicated that interaction between the gas and liquid phases inside a tube of 8.5 mm i.d. would be expected when the fluid lining layer was 0.5 mm or more. Fragmentation of the luminal surface of the fluid lining layer would be expected to occur at flow rates of 1 litre s^{-1}.

The 0.5-mm minimum thickness required for biofilm surface fragmentation was recorded at some point in the majority of tubes (74 %) examined in the present study. The figure of 74 % may underestimate the probability of biofilm surface fragmentation occurring if the biofilms demonstrated in this study were the residual, or stable remnants, left behind after loss of the more superficial layers.

The *in vitro* experiments referred to above [4] were conducted in a straight tube containing a fluid lining layer of constant viscosity. *In vivo*, the fluid dynamics of the tracheal tube lumen are complicated further by its curvature and by the bevelled end opening into a significantly wider tube. The lower end of the tracheal tube may therefore act as an asymmetrical diffuser [5]. The abrupt inrush of inspiratory phase gas into the proximal tracheal tube, the curvature of the tube and the narrowing of the tube lumen by biofilm may contribute to turbulent flow conditions favourable to biofilm surface fragmentation. It is equally possible that biofilm fragmentation may occur during the expiratory phase of ventilation. The contributions of surface tension effects, biofilm heterogeneity, boundary layers and other fluid phenomena were not examined in this study. Further work on fluid particle dissemination from the tracheal tube should assess the importance of these factors.

This combination of complex dynamic phenomena may explain the efficient scatter of bacteria already demonstrated in simulation experiments [2]. Evidence for dissemination of biofilm fragments during the inspiratory phase of ventilation is more difficult to obtain, but the microscopic particles and viable bacteria described on the patient side of used ventilator filters in the same report [2] are consistent with particle dissemination during expiration.

Although the process of tracheal tube biofilm deposition has yet to be studied in detail, it is presumed to be the result of a progressive accretion of ventilatory secretions. The absence of any clear relationship between maximum thickness and duration of tracheal tube was therefore unexpected. If confirmed in further studies, this suggests that the properties of residual biofilm, the flow conditions prevailing in the tube, or a combination of these factors, conspire to prevent further biofilm deposition.

Flow phenomena sometimes leave behind a permanent record of their occurrence in a more stable or static substratum, such as ripples left in the sand at low tide. The wave-like images seen in views of almost half the tubes examined in this study may represent a similar process. A lesser degree of two-phase flow would induce a slower velocity movement of the more viscous deeper layers of the biofilm. When this occurs near to the bevelled end of the tracheal tube during the inspiratory phase, it would increase the thickness of the fluid lining layer at the point where an asymmetrical diffuser effect may come into play, maximizing the loss of biofilm in this region. The absence of any zinc deposition in this area of maximum expected biofilm deposition, as seen in some tubes, is consistent with extensive biofilm loss.

Fluid dynamics is a largely empirical science, relying on simulation studies and careful observation. The complex dynamic phenomena occurring in the tracheal tubes of patients undergoing mechanical ventilation, reflected in biofilm distribution patterns observed in this study, require further investigation. The results of these investigations should help identify the flow characteristics of the ideal tracheal tube.

ACKNOWLEDGEMENTS

I am grateful to the staff of the Intensive Care Unit, Leeds General Infirmary for their assistance with this study, and to Mrs B. Clough and Dr D. J. Lintott for providing radiographic support.

PRESSURE EXERTED BY THE LARYNGEAL MASK AIRWAY CUFF UPON THE PHARYNGEAL MUCOSA

R. MARJOT

SUMMARY

Ten patients were studied for each of the sizes 2, 3 and 4 laryngeal mask airways (LMA) in order to calculate the pressure exerted by the cuff upon the pharyngeal mucosa. Using a non-invasive method of comparing intracuff pressures recorded both in vitro *and* in vivo, *the transmitted pharyngeal mucosal pressures were calculated over the clinical range of injection volumes. Cuff inflation with the "normal" injection volumes recommended resulted in the residual volumes of the cuffs being exceeded. The intracuff pressures recorded with the mask* in situ *at these normal injection volumes were in the range 103–251 mm Hg. The calculated transmitted mucosal pressures were substantial for all three sizes of cuff and potentially exceeded the capillary perfusion pressure of the adjacent pharyngeal mucosa, despite apparent pharyngeal accommodation to the mask.* (Br. J. Anaesth. 1993; **70**: 25–29)

KEY WORDS

Complications: mucosal pressure. Equipment: laryngeal mask airway.

The laryngeal mask airway (LMA) is an innovative new device for upper airway management. The prototype consisted of an elliptical cuff formed from the black rubber of a Goldman dental mask attached to a tracheal tube [1]. The currently manufactured model is constructed entirely from silicone rubber.

Inflation of the cuff orientates and positions the mask within the pharynx and creates a seal around the laryngeal inlet. This generates a pressure against the adjacent pharyngeal mucosa, sufficient to displace the thyroid and cricoid cartilages anteriorly [2] as the mask is "squeezed out of the triangular shaped base of the hypopharynx" [3].

It has been demonstrated that transmitted lateral wall pressure is the prime determinant of mucosal injury resulting from tracheal tube cuffs [4–6]. There has been one report of phayngeal trauma associated with repeated usage of an LMA within a short period [7]. The manufacturers currently recommend monitoring the LMA intracuff pressures to avoid postoperative throat discomfort [3].

The aim of this study was to determine the pharyngeal mucosal pressures generated by the sizes 2, 3 and 4 LMA with the cuff injection volumes used clinically.

PATIENTS AND METHODS

After Ethics Committee approval, informed written consent was obtained from 30 patients presenting for elective surgery for whom spontaneous ventilation via an LMA was appropriate [3].

The pilot tube of each LMA was attached via a three-way tap to a Spectramed pressure transducer (P10EZ) with a Physio Control VSM 1 recorder, and a Plastipak syringe (fig. 1). A 50-ml and a 10-ml syringe were used for the size 3 or 4 LMA and size 2 LMA, respectively. The same transducer was calibrated against a mercury column and the zero point determined before each study (non-linear error $< 2\%$). Each LMA was suspended in air and the cuff evacuated to a negative pressure of -20 mm Hg. The syringe volumes were adjusted so that they were equal for all the cases in each group of LMA. This was defined as the start point and, when set, this sealed system was not disrupted until the end of each study.

The pilot tube was clamped as it entered the cuff and a pressure–volume curve plotted to enable conversion of injected volume to cuff volume. This was necessary to account for the compression of the air within the inflating syringe, transducer, connecting tubing and pilot tube with pressurization of the system [8] (Appendix). The cuff was then inflated incrementally and the first pressure–volume curve of the cuff recorded (P1). The system was then aspirated back to the start point.

Anaesthesia was induced with propofol 1.5–3 mg kg^{-1} and spontaneous ventilation established with the patient breathing halothane and 67% nitrous oxide in oxygen. The laryngeal mask was inserted according to the manufacturer's instructions [3]. The patient's head and neck were then placed in a neutral position resting upon one pillow. The cuff was inflated incrementally *in situ* to record a second pressure–volume curve (P2).

At the end of surgery, the cuff was deflated *in situ* to record a third pressure–volume curve (P3). The laryngeal mask was removed from the patient and

Cuff residual volume (ml)	5.5 (0.6)	12.9 (0.9)	17.8 (1.9)
Anaesthetic time (min)	23.2 (10.2)	37 (12.4)	41.5 (16.7)
Cuff volume increase (%)	9 (0.5)	15.4 (7.6)	17.6 (5.2)
Cuff N_2O concn (%)	4.2 (1.3)	10.3 (3.1)	13.1 (4.8)

the cuff immediately reinflated. A fourth pressure–volume curve was recorded with deflation of the cuff whilst it was suspended in air (P4). The cuff was then aspirated back to the start point and the final volume within the syringe recorded.

The pilot tube was again clamped as it entered the cuff and a final pressure–volume curve plotted to enable conversion of injected volume to cuff volume [8] (Appendix). The gas was then aspirated back into the syringe and analysed immediately using a Datex Cardiocap monitor.

Cuff volume was calculated for each injected volume. Each pressure–volume curve (P1–P4) was replotted against cuff volume. Data presented refer to cuff volume.

For each cuff volume, the pharyngeal mucosal pressures for the start ($P\mathrm{pm}_s$) and end ($P\mathrm{pm}_e$) of anaesthesia were calculated. The cuff residual volume is that volume in excess of which the cuff develops sufficient tension itself to generate an intracuff pressure [9]. This intracuff pressure is determined from the pressure–volume curves P1 and P4. In order to obtain the pressure that any given cuff exerts upon the pharyngeal mucosa ($P\mathrm{pm}_s$ and $P\mathrm{pm}_e$), the intracuff pressure resulting from the tension in the cuff itself as its residual volume is exceeded (P1 and P4) is subtracted from the intracuff pressure recorded *in situ* (P2 and P3). Thus:

$$P\mathrm{pm}_s = \mathrm{P2} - \mathrm{P1}$$
$$P\mathrm{pm}_e = \mathrm{P3} - \mathrm{P4}$$

Data were analysed using analysis of variance for repeated measures (MANOVA). Values of $P < 0.05$ were considered significant. Data are presented as mean (SEM).

RESULTS

Observations were recorded for 10 patients using each LMA size (table I). The LMA was inserted successfully at the first attempt in 86% of the cases, and the remainder upon the second attempt. A clinically patent airway was provided in all patients.

Pressure–volume curves

The intracuff pressure increased for all three sizes of LMA with cuff inflation (fig. 2). The pressures recorded were significantly greater with the LMA *in situ* compared with inflation of the cuff whilst it was suspended in air (P2 *vs* P1 and P3 *vs* P4: $P < 0.001$). The cuff itself tended to be more compliant by the end of anaesthesia, but this was not significant (P1 *vs* P4: $P = 0.07$).

The cuff volume resulting from the injection of the manufacturer's "normal" recommended volumes exceeded the cuff residual volume for all three sizes of LMA (table I).

Pharyngeal mucosal pressures

There was an initial increase, followed by a plateau in the calculated transmitted pharyngeal mucosal pressures with increasing cuff volume (fig. 3). The largest calculated mean pharyngeal mucosal pressures were 79.9 (7) mm Hg, 92.3 (6.9) mm Hg and

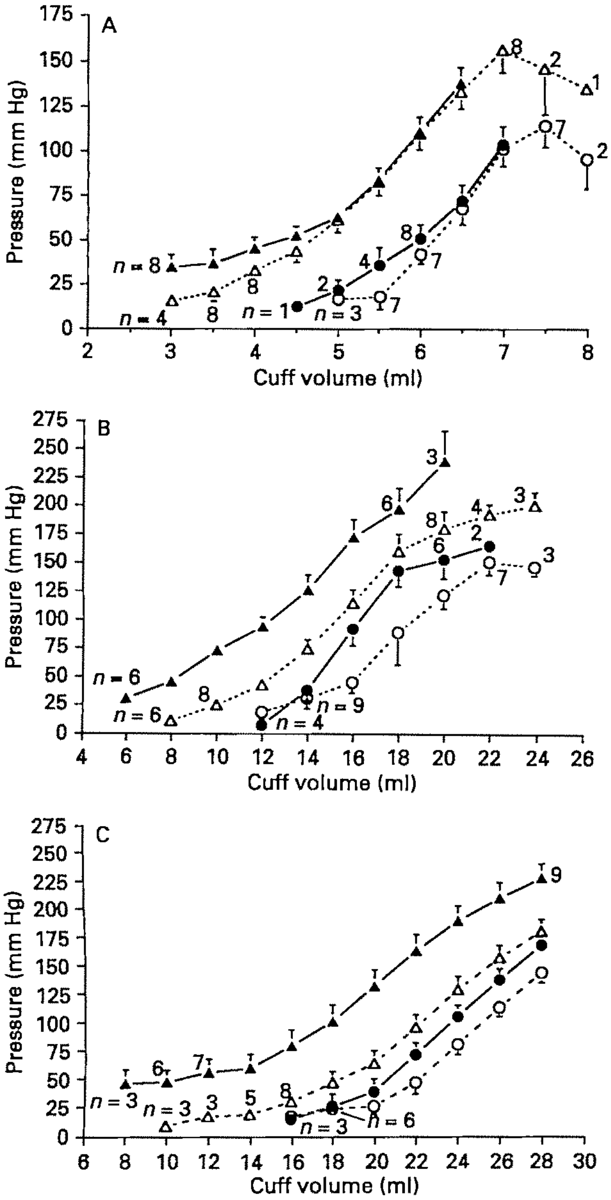

FIG. 2. The pressure–volume curves for P1 (▲), P2 (●), P3 (△) and P4 (○) for (A) size 2, (B) size 3 and (C) size 4 laryngeal mask airways, in 10 patients unless indicated otherwise.

93.1 (9.3) mm Hg for sizes 2, 3 and 4 LMA, respectively.

Using the size 4 LMA, a decrease in transmitted pharyngeal mucosal pressure occurred by the end of anaesthesia (Ppm_e) throughout the range of cuff volumes (fig. 3C). This reduction occurred only at the smaller range of cuff volumes with the sizes 2 and 3 LMA, with no reduction in the largest calculated mean mucosal pressures (fig. 3A, B).

The cuff volume increased in all three LMA groups by the end of anaesthesia. Nitrous oxide was detected in the gas aspirated from the cuffs (table I).

DISCUSSION

Laryngeal mask airway cuff inflation with the normal recommended injection volume [3] results in the residual volume of the cuff being exceeded. At these clinically used injection volumes, the features of a "low residual volume, high pressure cuff" were demonstrated.

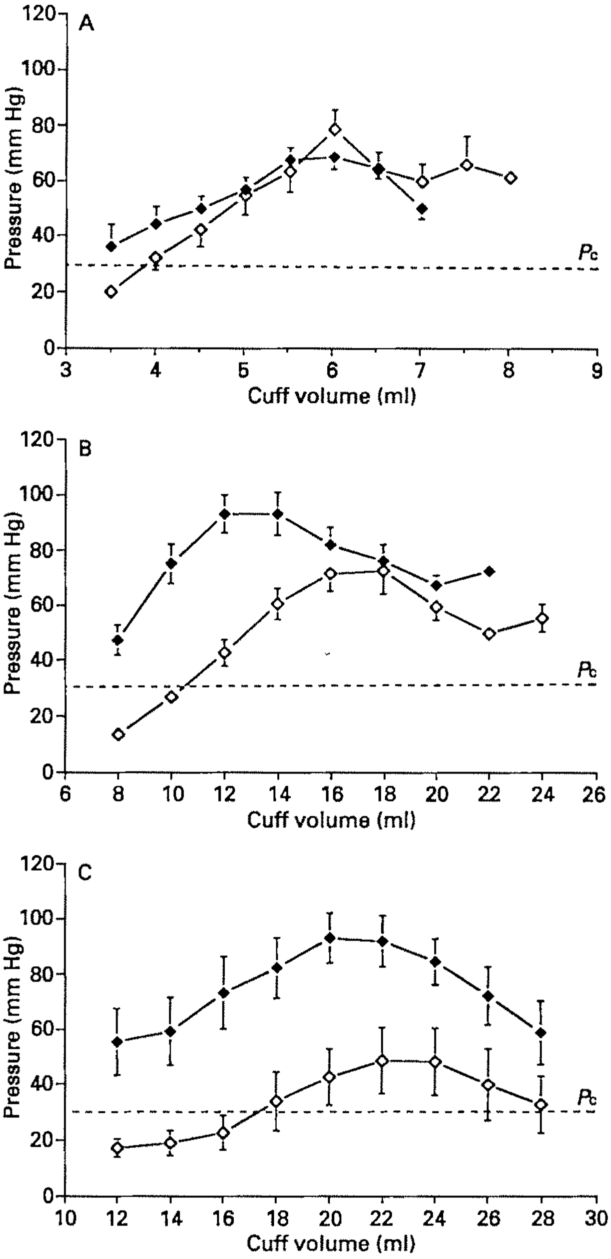

FIG. 3. The calculated pharyngeal mucosal pressures for the start (Ppm_s) (◆) and end (Ppm_e) (◇) of anaesthesia, for (A) size 2, (B) size 3 and (C) size 4 laryngeal mask airways. *Pc* is an estimate of mucosal capillary perfusion pressure.

The disadvantages of this cuff design have been described for tracheal tubes. Grimm and Knight [11] warned that the large intracuff pressure required to expand these cuffs to fill the trachea had the effect that an unknown pressure would be transmitted to the mucosa. Dobrin and Canfield [12] demonstrated that these cuffs, rather than conforming to the trachea, distort it, applying increasing pressure to the mucosa first encountered. McGinnis and colleagues [13] concluded that excessive lateral wall pressure was unavoidable if extensible occluding cuffs were used. This had led to the development of large-volume tracheal tube cuffs, enabling the maintenance of small intracuff pressure and therefore small lateral wall pressures.

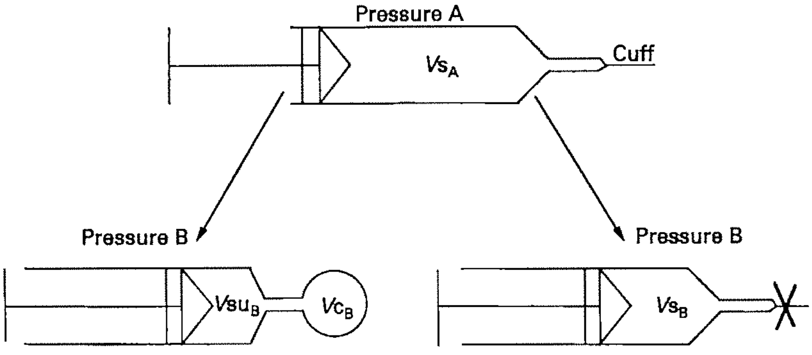

FIG. 4. Method of calculating cuff volume from injected volume.

Nordin [4] suggested that pressure was the principal determinant of cuff-induced tracheal mucosal morbidity, and demonstrated that cuff pressures exceeding 50 mm Hg, exerted upon the rabbit mucosa, resulted in partial denuding of the basement membrane. Seegobin and Van Hasselt [6] assessed fibreoptically the tracheal mucosa underlying the cuff in patients and observed that pressures exceeding 38 mm Hg resulted in total occlusion of mucosal blood flow.

Safe, prolonged tracheal intubation warrants a tracheal cuff that is compliant, deformable and inflated easily to a volume greater than the trachea with maintenance of the intracuff pressure less than 30 mm Hg [14].

For the cuffs of these sizes of LMA, the calculated transmitted lateral wall pressures were substantial when inflated with the recommended injection volumes and likely to exceed the pharnygeal mucosal capillary perfusion pressure (fig. 3).

Two features of the LMA cuff distinguish it from cuffs of tracheal tubes. First, there was not a sustained increase in transmitted lateral wall pressure with increasing cuff volume (fig. 3). Several factors could account for this. A degree of pharyngeal accommodation accompanying incremental cuff inflation might occur. Normally, there is cranial migration of the LMA in the hypopharynx as it is inflated [3], and the large intracuff pressure generated with the LMA *in situ* could result in configurational changes in the cuff, resulting in underestimation of the calculated transmitted pressure. In an evaluation of the methodology used in this study, Black and Seegobin [15] concluded that the derived pressures tended to be underestimates when the cuff became stretched, for this reason. The second distinguishing feature is that the transmitted lateral wall pressure decreased during the time the mask is *in situ* ($P\text{pm}_s$ *vs* $P\text{pm}_e$). Unlike the trachea, the pharynx is a fibromuscular tube which is capable of accommodating an object placed within it, such as an LMA. The apparent reduction in pharyngeal muscular tone with general anaesthesia [16] may also contribute to this decrease in pressure. The sizes 2 and 3 LMA demonstrated this phenomenon only at small cuff volumes. This could reflect a greater mask:pharyngeal size ratio which would limit any effect of pharyngeal accommodation.

An important advantage of the LMA is that insertion and removal do not require visualization of the airway. The incidence and degree of pharyngeal mucosal morbidity, therefore, remains undetermined; there has been one case report of trauma [7]. The incidence of postoperative sore throat with the LMA ranges between 7 and 12% [17–19]. Postoperative "dryness of the throat" was noted in 36% of patients in one study [19]. The aetiology of sore throat after general anaesthesia is multifactorial [20]. It correlates with the surface area of the cuff in contact with the mucosa, and not the lateral wall pressure generated by the cuff [21,22].

Cuff volume and intracuff pressure increased in all patients during anaesthesia. Nitrous oxide was detected in the gas from the cuffs. The gas concentrations recorded could be an underestimation as a result of the small sample volumes obtained for analysis by the Datex Cardiocap analyser. The 9–17.6% increases in cuff volume were less than the increases described previously for a range of tracheal tube cuffs exposed to nitrous oxide, even with consideration for the shorter anaesthetic time [23, 24]. The large intracuff pressure generated with the LMA *in situ* would increase the partial pressure of nitrous oxide within the cuff, decreasing the pressure gradient across the cuff wall, thereby limiting diffusion [23]. In addition, there may be a proportion of the cuff exposed to the air in the patient's upper pharynx, allowing nitrous oxide to diffuse back out of the cuff. Although nitrous oxide diffusion into the cuff increased cuff volume and intracuff pressure, this did not result in an increase in the pressure exerted upon the pharyngeal mucosa (fig. 3).

The site of the transmitted lateral wall pressure cannot be determined here. It is likely to differ in different parts of the pharynx, as the maximum cuff seal around the laryngeal inlet has been found to be only approximately 15 mm Hg [3].

The pharyngeal mucosal pressures demonstrated for the LMA are particularly unwarranted during spontaneous ventilation, as the cuff is not designed to secure the trachea from gastric aspiration, nor is it necessary for it to provide a high-pressure seal around the laryngeal inlet.

The pharyngeal mucosal pressures resulting from the LMA cuff depend, in a complex manner, upon the relative dimensions of the pharynx and LMA, the degree of accommodation by the pharynx and the inflation pressure required to extend the cuff sufficiently for its function as an airway. The morbidity resulting from this transmitted mucosal pressure is undetermined. It may be an important consideration when prolonged or repeated LMA usage is anticipated. Pressure upon the pharyngeal mucosa could be limited by reducing the cuff inflation volumes sufficiently so as not to exceed the residual volumes of the cuff. The intracuff pressure could then be monitored and maintained at a value less than expected mucosal capillary perfusion pressure. Intracuff pressure monitoring is now recommended by the manufacturers "to avoid postoperative throat discomfort" [3], although no guidelines are given as to an acceptable intracuff pressure. Lumb and Wrigley have suggested the fitting of a pressure relief valve to the cuff of the LMA [25]. The substantial reductions in cuff volume required to reduce intracuff pressure to less than expected capillary perfusion pressure may interfere with the function of the LMA with its current cuff design.

APPENDIX

The LMA is supported with the syringe and pressure recording system attached and sealed (fig. 1).

Pressure A = −20 mm Hg vacuum within cuff, pilot tube and syringe at the start.

Vs_A = Volume of air in syringe at pressure A (constant at 40, 26 and 10 ml for sizes 4, 3 and 2 LMA, respectively).

Temperature is assumed constant when comparing the pressure–volume curves P1 with P2, and P3 with P4, as P2 was recorded *immediately* after insertion and P4 *immediately* after removal of the LMA.

Then (fig. 4):

The pilot tube is clamped as it enters the cuff and the system is inflated to pressure B.

Vs_B = volume remaining in the syringe at pressure B.

Then:

The pilot tube is unclamped and the cuff inflated to pressure B.

Vsu_B = volume remaining within the unclamped syringe at pressure B.

Vc_B = cuff volume at pressure B.

Applying the gas law, $\frac{PV}{T}$ = constant.

$$\begin{aligned}\text{Pressure A} \times Vs_A &= \text{pressure B} \times Vs_B \\ &= \text{pressure B} \times Vsu_B + \text{pressure B} \times Vc_B\end{aligned}$$

Therefore:

$$Vc_B = Vs_B - Vsu_B$$

For example: the starting volume in the syringe for the size 4 LMA was 40 ml ($Vs_A = 40$). Injecting 30 ml caused an increase in pressure (pressure B) with a volume of 10 ml remaining in the syringe ($Vsu_B = 10$). Reinflating from the start point with the pilot tube now clamped to pressure B resulted in a volume of 32 ml remaining in the syringe ($Vs_B = 32$). Thus, with an injection volume of 30 ml, the cuff volume achieved was only $32 - 10 = 22$ ml.

This process was repeated to determine the cuff volumes resulting over the range of intracuff pressure achieved. This procedure was performed at the start of each study for the calculations regarding the pressure–volume curves P1 and P2 and repeated again following the removal of the LMA at the end of the study for the calculations regarding the pressure–volume curves P3 and P4.

COMPARISON OF THE REINFORCED LARYNGEAL MASK AIRWAY AND TRACHEAL INTUBATION FOR ADENOTONSILLECTOMY

P. J. WILLIAMS AND P. M. BAILEY

SUMMARY

*One hundred and four patients were allocated randomly to receive anaesthesia for adenotonsillectomy via either a reinforced laryngeal mask airway or a tracheal tube. Airway maintenance and protection were assessed during and after operation. The reinforced laryngeal mask did not interfere with surgical access; it resisted compression and protected the lower airway from contamination with blood. Four patients were withdrawn from the laryngeal mask airway group: two because of difficulty with placement, and two because the laryngeal mask was obstructed distally when the Boyle Davis gag was opened fully. In children, recovery was less eventful in the laryngeal mask airway group, with less airway obstruction (*P *< 0.001) and better airway acceptance (*P *< 0.05). The reinforced laryngeal mask airway provided a clear, secure airway until recovery of protective reflexes.* (Br. J. Anaesth. 1993; **70**: 30–33)

KEY WORDS

Anaesthesia: otorhinolaryngological. Equipment: laryngeal mask airway.

The laryngeal mask airway is made of silicone but, although the tube portion is relatively stiff, it is compressed or kinked easily and thereby obstructed. A modified laryngeal mask airway has been produced, with a reinforced tube portion which is suitable for use with a Boyle Davies gag, and its use in anaesthesia for adenotonsillectomy was described in 1990 [1].

Anaesthesia for adenotonsillectomy with tracheal intubation may be compromised by tracheal tube compression or displacement [2]. It subjects the patient to the complications of tracheal intubation [3], bronchial intubation with preformed tracheal tubes [4] and aspiration of blood past uncuffed tubes. Extubation at the end of surgery is performed either under deep anaesthesia, leaving an unprotected, insecure airway, or awake, risking excessive coughing and postoperative haemorrhage.

These problems might be avoided by using the modified laryngeal mask airway, as the tube portion is reinforced and resistant to compression and kinking. A correctly positioned laryngeal mask attains a gas-tight seal of up to 2 kPa [5] and has been shown to protect the larynx from dye placed in the pharynx [6].

The aim of this study was to compare the reinforced laryngeal mask airway with tracheal intubation for adenotonsillectomy.

PATIENTS AND METHODS

The study was approved by the Hospital Ethics Committee. Patients of ASA grades I and II, undergoing elective tonsillectomy and or adenoidectomy were allocated randomly (by the toss of a coin) to receive either a reinforced laryngeal mask airway or an RAE preformed orotracheal tube. Patients were not studied if there were any contraindications [5] to the use of a laryngeal mask airway, or if they weighed less than 15 kg. Patients were withdrawn if the quality of anaesthesia jeopardized either the patient or the success of surgery.

Children were premedicated with trimeprazine 2 mg kg^{-1} and atropine 0.02 mg kg^{-1} orally and EMLA cream was applied to the dorsum of both hands 1.5 h before operation. Adults received papaveretum 0.2 mg kg^{-1} i.m. and hyoscine 0.004 mg kg^{-1} 1 h before operation.

Anaesthesia was induced with thiopentone 5 mg kg^{-1} or halothane in 50% nitrous oxide and oxygen. Tracheal intubation was facilitated by administration of suxamethonium 1 mg kg^{-1} i.v. and, in children, the correct tube size was confirmed by demonstration of a small leak with positive pressure ventilation. The laryngeal mask was inserted without the use of a neuromuscular blocker when the patient did not respond to jaw lift, and correct placement was confirmed by the presence of a clinically clear airway and the ability to inflate the patient's lungs manually with no audible gas leak.

Anaesthesia was maintained by spontaneous breathing of 66% nitrous oxide in oxygen and 1–1.5% halothane. Patients were placed supine with a shoulder bar and pillow removed to extend the neck. Monitoring comprised pulse oximetry, capnography, ECG and automated non-invasive arterial pressure.

*Present address, for correspondence: Department of Anaesthesia, Lewisham Hospital, Lewisham High Street, London SE13 6LH.

At the end of surgery, the pharynx was cleared of blood under direct vision and, in the tracheal tube group, the larynx was viewed to detect any blood on the vocal chords. Patients then breathed 100% oxygen with halothane for 3 min, after which an Olympus LE1 fibreoptic bronchoscope was passed down either the laryngeal mask, to inspect the larynx and interior of the mask, or the tracheal tube, to view the trachea. The bronchoscope was not passed beyond the end of the tracheal tube.

All patients were placed in the left lateral position with a pillow under the shoulder during recovery. The laryngeal mask was left *in situ*, while the tracheal tube was removed and a Guedel airway used to aid airway maintenance. All patients were monitored with pulse oximetry and received 40% oxygen until awake.

All anaesthetics were given by the authors and surgery was performed by surgeons of all grades who were familiar with the procedure. Neither the anaesthetist nor the surgeon was randomized.

Data were analysed using Student's t test and χ^2 test for 2×2 contingency tables with Yates' correction.

RESULTS

Patient characteristics and surgical procedure for the two groups are shown in tables I and II. Although the tracheal group appear younger and lighter, the difference is not significant statistically.

One hundred and four patients were recruited, but four patients were withdrawn from the laryngeal mask group (table III): two because of difficulty with laryngeal mask insertion, and two because the laryngeal mask airway became obstructed when the Boyle Davis gag was opened fully. In one of the last two, surgical access was inadequate.

In the remaining patients, surgical access (table IV) was good or adequate, with the laryngeal mask airway being hidden from view when the Boyle Davis gag was opened fully.

There were no episodes of airway obstruction in either group in the remaining patients.

One laryngeal mask airway was displaced by the laryngoscope during pharyngeal toilet at the end of surgery. It was repositioned easily while *in situ* and no aspiration of blood occurred.

Laryngeal spasm occurred in three patients—once on tracheal extubation, which was treated with 100% oxygen; no desaturation occurred. In the laryngeal mask group, insertion of the Boyle Davis gag induced laryngeal spasm in one patient because of inadequate depth of anaesthesia. This was treated by deepening anaesthesia with i.v. thiopentone and manual ventilation; desaturation was prevented. The third episode resulted from accidental laryngeal stimulation during fibreoptic inspection of the inside of the laryngeal mask and larynx. This was the only case of oxygen desaturation (to 75%) during operation and it was treated with i.v. suxamethonium 50 mg and manual ventilation with 100% oxygen via the laryngeal mask.

Oxygen desaturation (< 94%)	1*	0	> 0.5

Where there were statistically significant differences between the groups, we have analysed the results according to age because the incidence of perioperative aspiration and postoperative airway obstruction, in particular, varied with age in the tracheal tube group. Aspiration of blood into the lower airway occurred frequently in the intubation group (table V), particularly in children, extending past the carina in three children. However, in the laryngeal mask airway group, there were no cases of aspiration of blood into the larynx ($P < 0.001$) and only one instance when a small amount of blood entered a laryngeal mask. The presence of blood in the lower airway of children (table VI) was associated

with an increase in coughing during recovery ($P < 0.05$). There were no cases of perioperative blood loss requiring i.v. fluid replacement (i.e. loss greater than 10 % of calculated blood volume) and no episodes of postoperative haemorrhage.

In children, maintenance of an unobstructed airway during recovery (table VII) was much easier with the laryngeal mask airway than with the Guedel airway ($P < 0.001$) and airway acceptance was better ($P < 0.05$). Suction to clear secretions and blood was easy in both groups, but was required less in the tracheal intubation group ($P < 0.05$). In adults, a similar pattern was observed for airway maintenance and acceptance and the need for suction during recovery, but the number of adults studied was too small to show a statistically significant difference.

Oxygen desaturation to 92 %, 90 % and 88 % occurred in three children in the intubation group; two cases resulted from laryngeal spasm and one from upper airway obstruction. One patient required further surgery to control bleeding detected while the laryngeal mask was still in place. Anaesthesia was deepened and haemostasis achieved.

DISCUSSION

Our results show that the reinforced laryngeal mask airway may be used in place of tracheal intubation during anaesthesia for adenotonsillectomy.

It is noteworthy that the laryngeal mask airway did not obstruct the surgical field and, when the Boyle Davis gag was opened fully, the surgeon could not distinguish between it and a tracheal tube. Adequate, rather than good, surgical access occurred in children in both groups. In addition, the laryngeal mask airway protected the lower airway from aspiration of blood during operation; in contrast, in the intubation group, aspiration of blood occurred in 54 % of children and 15 % of adults.

Although we did not see the trachea in the laryngeal mask group, we have assumed the trachea was not contaminated because there were no cases of laryngeal contamination and only one case of blood entering the laryngeal mask airway by the end of surgery.

Four children had to be withdrawn from the laryngeal mask group, two because the laryngeal mask became obstructed and two because it proved impossible to place the reinforced laryngeal mask correctly. This was caused by very large tonsils causing the mask portion to rotate on the flexible tube of the laryngeal mask airway.

The airway was compromised in three patients in the laryngeal mask group. One patient developed mild laryngeal spasm on insertion of the Boyle Davis gag, and this highlights the need to ensure adequate depth of anaesthesia. In two children with small, narrow, long mouths and restricted mouth opening, the reinforced laryngeal mask airway was obstructed distally when the Boyle Davis gag was opened fully. This was probably a result of the gag pushing the laryngeal mask anteriorly, causing the aperture to be occluded by the epiglottis, which may also have been down-folded. Such cases, when identified, require tracheal intubation, but it must be remembered that occasionally, in patients with severely limited surgical access, the Boyle Davis gag must be inserted asymmetrically to avoid tracheal tube compression, and one tonsil removed before repositioning the gag to remove the other tonsil.

With the exception of the above three patients and the iatrogenic case of laryngeal spasm, the laryngeal mask airway provided as clear an airway as the RAE tube. It is of note that while the Boyle Davis gag is *in situ* the laryngeal mask airway (or the RAE tube) is held firmly in place by the gag and displacement is unlikely to occur.

One laryngeal mask airway was displaced during pharyngeal toilet. This occurred because the laryngoscope blade elevated the tongue base, allowing the laryngeal mask airway to slip up over it. This can be avoided if care is taken to elevate the mask portion of the laryngeal mask airway and the tongue base together.

It is advocated that the laryngeal mask airway be left in place to ensure a clear airway until recovery of protective reflexes [5]. Our results support this view, as only two patients had problems during recovery. One child developed mild laryngeal spasm and required mandibular support, and one adult coughed on the laryngeal mask, without ill effect. This compares with frequent airway obstruction and coughing and occasional laryngeal spasm and oxygen desaturation when a Guedel airway was used to aid airway maintenance. The cause of upper airway obstruction during anaesthesia is complex [7] and the Guedel airway itself has been associated with causing airway obstruction [8]. These problems can be overcome by leaving the laryngeal mask *in situ* for recovery from anaesthesia.

Suction to clear excessive amounts of blood and secretions pooling in the mouth was required more often in the laryngeal mask group, especially in children, and may be necessitated by the laryngeal mask preventing these fluids from being swallowed or aspirated.

On removal, all laryngeal mask airways were blood-stained on their outer surfaces and in masks from eight patients there was blood staining on the inner surface. We cannot know if this occurred while the laryngeal mask airway was still in place, or during its removal. Of these eight patients, only one child developed mild laryngeal spasm and in the others there were no signs of aspiration of blood. In the Guedel airway group, nine patients coughed, five developed laryngospasm and three suffered oxygen desaturation, possibly suggesting laryngeal contamination during recovery.

The reinforced laryngeal mask airway has been used previously for adenotonsillectomy anaesthesia [1], but there was no direct assessment of laryngeal protection. When 10 ml of methylene blue was placed in the oropharynx [6] there were no cases of laryngeal contamination with dye, although the site of surgery was not specified. We have shown that the laryngeal mask airway did protect the larynx from contamination with blood during surgery on the upper airway.

The laryngeal mask airway is contraindicated in non-fasted patients, in whom there is risk of regurgitation of stomach contents, and in patients with low lung compliance [5]. However, patients with these problems rarely present for elective adenotonsillectomy.

COMPARISON OF ALFENTANIL WITH SUXAMETHONIUM IN FACILITATING NASOTRACHEAL INTUBATION IN DAY-CASE ANAESTHESIA

R. ALCOCK, T. PEACHEY, M. LYNCH AND T. McEWAN

SUMMARY

We have performed a prospective study in 100 adults (ASA I or II) undergoing day-case dental extraction to compare the conditions for intubation and the postoperative sequelae of suxamethonium and alfentanil as adjuncts to propofol. The patients were allocated randomly to two groups comparable in age, sex and weight. Successful intubation was achieved in 100% of the suxamethonium group and 90% of the alfentanil group. Of the patients who received suxamethonium, 74% developed myalgia on the day after surgery, compared with 20% in the alfentanil group ($P < 0.001$). The proportion of patients who developed sore throat was also less in the alfentanil group than in the suxamethonium group ($P < 0.05$). The proportion of patients who complained of nausea in the two groups was not significantly different. We conclude that alfentanil, as an adjunct to propofol to facilitate tracheal intubation, is more acceptable to patients than suxamethonium in anaesthesia for day-case surgery. (Br. J. Anaesth. 1993; **70**: 34–37)

KEY WORDS

Anaesthesia: day-case. Anaesthetics, intravenous: propofol. Analgesics: alfentanil. Intubation tracheal: complications. Neuromuscular relaxants: suxamethonium.

Suxamethonium has several disadvantages: it may cause bradycardia, anaphylactoid reactions, and an increase in serum potassium concentration, and is a trigger agent for malignant hyperpyrexia. Additionally, the use of suxamethonium is associated with postoperative muscle pains in a significant proportion of patients. In most patients these amount to no more than mild stiffness, but occasionally they may be disabling [1]. Myalgia most often affects the neck, shoulder girdle and abdomen, appearing during the first and second days after surgery. It occurs more often in ambulant patients, with women affected more than men [2]. It is rare in children [3] and the elderly [4].

Many methods have been tried to abolish these pains, such as pretreatment with gallamine, vecuronium, midazolam and aspirin. Pretreatment with a non-depolarizing neuromuscular blocker attenuates the fasciculations which herald the onset of relaxation [5]. The degree to which myalgia may be reduced by pretreatment varies [5–7].

An alternative approach to the use of suxamethonium for tracheal intubation is to use propofol, either alone or in combination with lignocaine [8, 9]. In our experience, a standard induction dose of propofol 2.5 mg kg^{-1} provides inadequate muscle relaxation in unpremedicated patients. Therefore, rather than increase the dose of propofol, which has the potential to cause excessive cardiovascular depression, we decided to combine it with the rapidly acting opioid alfentanil in an attempt to produce adequate depth of anaesthesia for tracheal intubation.

PATIENTS AND METHODS

Approval for the study was granted by the Joint Research and Ethics Committee of the Eastman Dental Hospital and informed consent was obtained from all patients. We studied 100 adults presenting for day-case extraction of wisdom teeth under general anaesthesia. All patients were ASA I or II and unpremedicated. Patients were allocated randomly to two groups. In group A, anaesthesia was induced with propofol 2.5 mg kg^{-1} followed by suxamethonium 1 mg kg^{-1} to facilitate tracheal intubation. Group B received alfentanil 10 μg kg^{-1} followed by propofol 2.5 mg kg^{-1}. In both groups, after ventilation of the lungs with 100% oxygen, the trachea was intubated with an uncuffed red rubber nasotracheal tube, and a throat pack inserted. If conditions in group B were such that intubation was not possible, the patients were then given suxamethonium 1 mg kg^{-1} to facilitate intubation. Anaesthesia was maintained with 70% nitrous oxide in oxygen supplemented by a volatile agent (halothane or isoflurane) as indicated clinically. Ventilation was controlled until spontaneous breathing returned. The patients were monitored with an electrocardiogram, a non-invasive arterial pressure monitor and a pulse oximeter.

At the end of the procedure, the tracheal tube was removed while the patient was still deeply anaesthetized. Postoperative pain was controlled with a codeine–aspirin combination (Co-codaprin).

The anaesthetist scored the quality of intubating conditions on the following scale: 1 = excellent—blind nasal or jaw relaxed, cords abducted with no movement on passage of the tube; 2 = good—cords abducted, jaw relaxed, some movement on intubation; 3 = poor—cords adducted, difficulty in opening mouth or movement on intubation; 4 = suxamethonium required for successful intubation of the trachea.

A telephone questionnaire was performed on the day after surgery by an anaesthetist who did not know to which group the patient belonged. The patient was questioned for the presence and severity of: aches, pains and muscle stiffness; sore throat; nausea or vomiting. For each, answers were graded as none, slight, moderate or severe. The patient was also invited to report any other problems relating to their operation.

Data were analysed statistically using chi-square with Yates' correction and Fisher's exact test.

RESULTS

Both groups were well matched for age, weight and sex (table I).

Overall, intubation was accomplished in 100% of the patients in group A and intubating conditions were described as good or excellent in all (table II).

TABLE I. *Age, weight and sex distribution (number, or mean (range or SD))*

	Group A (n = 50)	Group B (n = 50)
Sex (M:F)	14:36	16:34
Age (yr)	28.5 (16–69)	26.7 (17–57)
Weight (kg)	64.1 (11.0)	64.1 (12.1)

Intubation was accomplished without suxamethonium in 45 patients (90%) in group B and intubating conditions were described as good or excellent in 43 patients (86%). Although the proportion of successful intubations was less in men (81%), the difference between the sexes was not statistically significant.

In all five patients from group B who received suxamethonium, failure to intubate the trachea when propofol and alfentanil were used was caused by inadequate depth of anaesthesia.

Overall, 37 patients (74%) in group A suffered muscle pains of any severity as opposed to nine patients (20%) in group B ($P < 0.001$) (table III). Of the men, nine (64%) in group A and five (38%) in group B suffered pains of some type (ns). Of the women, 28 (78%) in group A and four (12%) in group B suffered pains ($P < 0.001$).

The frequency of moderate or severe pain was compared with slight or no pain. Twenty-one patients (42%) in group A, compared with three patients (7.0%) in group B suffered moderate or severe pain ($P < 0.001$). Of the men, four (28%) in group A and one (7%) in group B suffered moderate or severe pains ($P = 0.16$). Of the women, 17 (47%) in group A and two (6%) in group B suffered pains ($P = 0.0013$). There was no significant difference between the sexes.

All five patients in group B who received suxamethonium, reported either moderate or severe pain on the day after surgery.

Overall, 41 patients (82%) in group A and 24 patients (53%) in group B complained of sore throat ($P < 0.05$) (table IV). The differences in both men and women between the suxamethonium group and the alfentanil group were significant ($P = 0.033$ and $P = 0.021$, respectively). There was no significant difference between the sexes. There was no significant difference in the reporting of moderate or severe sore throat between the groups.

The number of people reporting nausea of any degree was five (10%) in group A and six (15%) in

group B (ns). Only two people in each group reported anything other than slight nausea. There was no significant difference between the sexes.

All other problems reported ($n = 28$) related to pain and swelling at the operative site. There was no significant difference between the two groups (15 in group A and 13 in group B).

DISCUSSION

Our overall success rate of 90%, intubating with propofol and alfentanil, compares favourably with the 95% reported by Keaveny and Knell [8] who successfully intubated the trachea of 19 of 20 patients with propofol alone. Mullholland and Carlisle achieved intubation in 73% of a group of 30 patients using propofol supplemented by lignocaine 1.5 mg kg^{-1} [9]. In our study, intubating conditions were good or excellent in 86% of patients, compared with 60% and 67%, respectively, in the above studies.

Muscle pains after suxamethonium may occur in up to 85% of patients [4]. The 74% incidence noted in our study is comparable to the 66% quoted by Churchill-Davidson in his group of 32 outpatients [1]. Although a greater percentage of women than men complained of muscle pains, the difference was not statistically significant. A difference between the sexes has been described by other authors [2]. The proportion of patients who received suxamethonium and developed moderate or severe pains was 42% in our study. We believe this incidence is unacceptable.

The overall reduction in muscle pains on the day after surgery to 20% in the alfentanil group compares favourably with the reductions achieved by other investigators who pretreated patients receiving suxamethonium with other drugs. Bennetts and Khalil [6] observed muscle pains in 68% of their untreated patients. The frequency of muscle pains was reduced, at best, to 28%, by pretreatment with pancuronium 1 mg and, at worst, to 50% by pretreatment with tubocurarine 2.5 mg. Mingus, Herlich and Eisencraft [5] reduced the frequency of pains on the day after surgery from 70% to 45% by pretreating with tubocurarine 0.05 mg kg^{-1}. The use of vecuronium 0.006 mg kg^{-1} or midazolam 0.025 mg kg^{-1} was less effective. McLoughlin, Nesbitt and Howe [7] reduced postoperative myalgia from 57% in their untreated group to 21% using aspirin 600 mg given orally before operation.

The significantly greater frequency of sore throat in the suxamethonium group was an unexpected finding. We had felt that the increased manipulation of the tracheal tube which is sometimes necessary to achieve intubation in the alfentanil group, might make these patients more liable to sore throat. This difference remains unexplained. The overall frequency of sore throat in both groups was large in comparison with other studies of postoperative morbidity [10]. However, we are unaware of any study on postoperative sore throat in day-case patients undergoing dental extraction.

It is interesting to note that the frequency of nausea was not significantly greater in the alfentanil group than in the suxamethonium group, probably because of the short duration of action of alfentanil. No patient required treatment with antiemetic agents.

On the basis of this study, we believe that alfentanil may be an alternative to suxamethonium as an adjunct to propofol in facilitating tracheal intubation. Its use was associated with a significant decrease in postoperative myalgia without an increase in the frequency of other side effects such as sore throat and nausea. We feel that, in combination with propofol, it is suitable for use in young ambulant patients requiring intubation for day-case surgery. However, with the doses used in this study there was a 10% failure rate. To those wishing to attempt this technique, we make the following recommendations: intubation with propofol and alfentanil should not be attempted if the operator is unfamiliar with the technique of nasotracheal intubation of if difficulty in intubation is anticipated; suxamethonium should be available, drawn up into a syringe; following treatment with alfentanil 10 μg kg^{-1}, propofol should be administered in a dose sufficient to cause relaxation of the jaw (in some patients this may exceed the dose of 2.5 mg kg^{-1} used in this study); suxamethonium should be administered if the cords are not visualized at direct laryngoscopy because of muscular resistance, if there is complete adduction of the cords of if there is a prolonged bout of coughing.

EFFECT OF AGE, GENDER AND ANAESTHETIC TECHNIQUE ON THE PHARMACODYNAMICS OF ATRACURIUM

C. J. R. PARKER, J. M. HUNTER AND S. L. SNOWDON

SUMMARY

We have measured in 38 patients the plasma concentration profile of atracurium and its effect on the electromyographic first response of the train-of-four. One of three techniques was used to supplement anaesthesia with 66% nitrous oxide in oxygen, 0.9% isoflurane (end-tidal), 0.5% halothane (end-tidal) or midazolam 3–10 mg. A four-parameter threshold pharmacodynamic model was fitted to the data in each patient. Compared with a group of patients anaesthetized with an i.v. technique, the steady-state plasma concentration producing 50% block ($C_P^{ss}{}_{50}$) was reduced by halothane, and to a greater extent by isoflurane. The rate constant for exit from the effect compartment (k_{e0}) correlated negatively with age and was greater in female patients, but unaffected by anaesthetic technique. The values of γ, the slope of the concentration–response curve, and of the threshold ($C_P^{ss}{}_0$) were not affected significantly by age, sex or anaesthetic technique. (Br. J. Anaesth. 1993; **70**: 38–41)

KEY WORDS

Age factors. Neuromuscular relaxants: atracurium. Pharmacodynamics.

Volatile anaesthetic agents potentiate the action of the non-depolarizing neuromuscular blocking drugs [1], and isoflurane is more potent than halothane in equivalent MAC multiples *in vivo* [2–4]. The best attempts to analyse this phenomenon have used an effect compartment model; thus tubocurarine was shown to be potentiated by halothane at its site of action, an effect manifest by a dose-dependent decrease in the parameter $C_P^{ss}{}_{50}$, whilst 1.2% halothane (end-tidal) diminished the rate of equilibration of tubocurarine with its site of action [5]. In pharmacodynamic studies, atracurium was shown to be potentiated by 0.75% isoflurane (end-tidal), which produced a decrease of 18% in the ED_{50} [6], and by 0.8% halothane (end-tidal) which, in children, produced a decrease in the ED_{50} from 170 to 130 μg kg^{-1} [7]. The potentiation of atracurium by volatile anaesthetic agents has not been analysed using an effect compartment model.

Previous pharmacodynamic studies of atracurium have failed to reveal an effect of ageing on the infusion requirements for sustained neuromuscular block [8], in contrast with vecuronium, for which advanced age reduces the infusion requirements [9]. The neuromuscular blocking effect of atracurium has been analysed previously with the aid of a standard effect compartment model at the extremes of age [10, 11]; the number of patients was small however, and the results were essentially negative. Similarly, advanced age had little effect on the parameters of the standard pharmacodynamic model for pancuronium and vecuronium [12]. The effect of gender on pharmacodynamics of non-depolarizing neuromuscular blocking drugs has not been studied previously.

We have analysed the action of atracurium on the first response of the train-of-four using the threshold pharmacodynamic model [13], in healthy adult patients and examined the effect of age, gender and anaesthetic technique on the pharmacodynamic model parameters.

PATIENTS AND METHODS

We studied 38 healthy patients undergoing minor surgery requiring the use of neuromuscular block. The study was approved by the Ethics Committee of the Royal Liverpool Hospital and informed consent was obtained from all patients. The patients (table I) were allocated to three groups, which differed only in the technique used to maintain anaesthesia.

Premedication was given as reported previously [14]. Anaesthesia was induced with fentanyl 25–200 μg and thiopentone 250–500 mg. Anaesthesia

C. J. R. PARKER, M.A., M.D., F.R.C.ANAES.; J. M. HUNTER, M.B., F.R.C.ANAES.; S. L. SNOWDON, M.B., CH.B., F.R.C.ANAES.; University Department of Anaesthesia, 4th Floor, Royal Liverpool Hospital, Prescot Street, P.O. Box 147, Liverpool L69 3BX. Accepted for Publication: July 17, 1992.

was maintained with 0.9% isoflurane (end-tidal) and 66% nitrous oxide in oxygen (group I), 0.5% halothane (end-tidal) and 66% nitrous oxide in oxygen (group II) or with no volatile anaesthetic agent but with 66% nitrous oxide in oxygen supplemented with i.v. midazolam 3–10 mg. End-tidal concentrations of volatile anaesthetic agents were monitored using an infra-red absorption monitor (Datex, Normac).

After induction of anaesthesia, train-of-four electromyographic monitoring was commenced using a Medelec MS6. Two i.v. cannulae were sited, one in each arm: one was used for withdrawal of blood samples, the other for administration of atracurium.

Twenty minutes after induction of anaesthesia, when an electromyographic baseline was established and the end-tidal concentration of volatile anaesthetic agent (if used) was stable, atracurium 0.25 mg kg^{-1} was given by constant rate infusion over 10 min. Ventilation was controlled and the trachea intubated when appropriate; end-tidal carbon dioxide partial pressure was maintained in the range 4.0–5.3 kPa (Datex, Capnomac). Pharmacological antagonism of neuromuscular block was not used.

Blood samples (2.5 ml) were taken before and at 1, 2, 4, 6, 8 and 10 min after the start of the infusion, and at 1, 2, 4, 6, 8, 10, 15, 20, 25, 30, 40, 50, 60, 75 and 90 min after the infusion. The heparinized blood samples were immediately acidified and cooled, and plasma was separated promptly. The plasma was frozen rapidly in liquid nitrogen and stored at −20 °C until subsequent analysis for plasma atracurium concentration by HPLC as described previously [14]. The analysis was performed in duplicate with a coefficient of variation between duplicates typically of less than 6% (range 1.6–11.1%).

Data analysis

A threshold pharmacodynamic model was fitted to the data for each patient [13]. This model is characterized by four parameters: the plasma concentration which would, at steady state, produce 50% block ($C_P^{ss}{}_{50}$); the slope of the concentration–response relationship (γ); the rate constant for exit of drug from the effect compartment (k_{eo}); and the steady-state plasma concentration which would just fail to evoke any effect ($C_P^{ss}{}_{\theta}$). A least-squares criterion was used without any attempt to assign different weights to the pharmacodynamic data points.

Comparisons between groups were performed using the Fisher protected LSD test; comparisons between the sexes were made using the Mann–Whitney test. The relationship between pharmacokinetic variables and age was examined by Pearson's correlation coefficient. Where a variable appeared to be affected by more than one explanatory factor, multivariate linear regression was applied; the significance of added regressors was tested using the *F* test.

RESULTS

The pharmacodynamic model parameters are summarized as mean (SD) for each group (table II).

TABLE II. *Mean (SD) values of the pharmacodynamic model parameters for each group. Possible differences between the groups were evaluated using the Fisher LSD test.* ****Significant difference amongst the three groups* (P < *0.005*)

	Isoflurane	Halothane	Midazolam
$C_P^{ss}{}_{50}$***	357	432	524
(ng ml^{-1})	(65)	(82)	(116)
γ	2.38	2.26	2.44
	(0.31)	(0.32)	(0.35)
k_{eo}	0.119	0.119	0.120
(min^{-1})	(0.025)	(0.038)	(0.023)
$C_P^{ss}{}_{\theta}$	160	176	225
(ng ml^{-1})	(40)	(62)	(91)

TABLE III. *Univariate correlation of certain pharmacodynamic model parameters with age, patients in all three groups considered together. The negative correlation of* k_{eo} *with age is highly significant. In view of the difference in* $C_P^{ss}{}_{50}$ *between the groups, the relationship for this parameter was evaluated using multivariate regression (see text) and is not shown here*

Parameter	*r*	d.f.	*P*
γ	−0.300	36	> 0.05
k_{eo} (min^{-1})	−0.507	36	< 0.005
$C_P^{ss}{}_{\theta}$ (ng ml^{-1})	−0.040	36	> 0.1

Effect of anaesthetic technique

$C_P^{ss}{}_{50}$ tended to be greatest in the patients anaesthetized without a volatile anaesthetic agent, and least in the patients anaesthetized with isoflurane; patients anaesthetized with halothane occupied an intermediate position. The difference amongst the groups was statistically significant ($F = 9.93$; 2,35 d.f.; $P < 0.005$).

Application of the Fisher LSD test showed that $C_P^{ss}{}_{50}$ was greater in patients anaesthetized with midazolam than with halothane ($P < 0.05$), and greater in patients anaesthetized with halothane than with isoflurane ($P < 0.05$).

The values of $C_P^{ss}{}_{\theta}$ also tended to be greatest in patients anaesthetized without a volatile anaesthetic agent and least in patients anaesthetized with isoflurane, but the differences between groups were not significant ($F = 2.88$; 2,35 d.f.; $P > 0.05$).

The values of γ and of k_{eo} were not significantly different between the three groups.

Effect of age

The univariate correlation of the values of the parameters γ, k_{eo} and $C_P^{ss}{}_{\theta}$ with age, for all patients, is shown in table III. Whereas the values of γ and $C_P^{ss}{}_{\theta}$ did not correlate significantly with age, there was a strong negative correlation between the values of k_{eo} and age.

The possibility of an effect of age on the values of $C_P^{ss}{}_{50}$ was assessed by multivariate regression, taking account of the effect of anaesthetic technique; age was not a statistically significant regressor ($F = 0.33$; 1,34 d.f.; $P > 0.1$).

Effect of gender

The effect of gender on the value of k_{eo} was examined by multivariate regression (table IV). It

TABLE IV. *The bivariate regression of* k_{eo} *(*min^{-1}*) on age and gender. The intercept is the hypothetical value of* k_{eo} *in a female, aged 0 yr. On average the value of* k_{eo} *is 0.024* min^{-1} *greater in female than male patients, and declines by* 9.9×10^{-4} min^{-1} *per year of increasing age. The values of* F *for the inclusion of each variable in the regression are shown, together with the degrees of freedom of the numerator and denominator, and the associated values of* P. *The correlations of* k_{eo} *with age and gender are both statistically significant*

Variable	Regression coefficient	SE	F	d.f.	*P*
Intercept	0.167	0.120	—	—	—
Age (yr)	-9.9×10^{-4} ($\mathrm{min}^{-1}\ \mathrm{yr}^{-1}$)	3.0×10^{-4}	10.7	1,35	< 0.005
Sex (M = 1; F = 0)	−0.024 (min^{-1})	0.008	8.73	1,35	< 0.01

can be seen that gender had a statistically significant effect; k_{eo} was on average 0.024 min^{-1} greater in female than male subjects. Multivariate regression taking account of age and gender, and two additional parameters to separate the groups, failed to show an effect of anaesthetic technique on k_{eo}.

The possible effect of gender on the value of $C_P^{ss}{}_{50}$ was evaluated by multiple regression, taking into account the effect of anaesthetic technique. The difference between the sexes was not significant ($F = 3.16$; 1,34 d.f.; $P > 0.05$).

When the patients from all three groups were considered together, there was no significant difference between the sexes in the values of γ ($P > 0.1$) or $C_P^{ss}{}_{\theta}$ ($P > 0.1$).

DISCUSSION

The use of an effect compartment model allows definition of the influence of the volatile anaesthetic agents on the action of a non-depolarizing neuromuscular blocking drug; effects on the sensitivity of the site of action may be differentiated from effects on the access of drug to the end-plate. This study is the first to do so for atracurium. Main findings were that atracurium-induced neuromuscular block was potentiated by both halothane and isoflurane (as shown by a reduction in $C_P^{ss}{}_{50}$), and that isoflurane was more potent in this respect in the concentrations used.

The end-tidal concentrations of halothane and isoflurane were chosen to represent 66–70% of 1 MAC (0.74% for halothane [15]; 1.28% for isoflurane [16]). The volatile anaesthetic concentration was not adjusted to take account of the decrease in MAC with age. Physical considerations suggest that equilibration of the volatile anaesthetic agent with the muscle was unlikely to be complete when the atracurium infusion was started. The choice of a 20-min period was pragmatic, but there is evidence, at least for halothane, that potentiation of the effect of non-depolarizing neuromuscular block is largely complete after 10 min [17].

The relative potency of equal MAC multiples of the two agents in reducing $C_P^{ss}{}_{50}$ agrees with the results of previous purely pharmacodynamic work with older non-depolarizing neuromuscular blocking drugs in the human [2–4]. However, a careful study *in vitro* of the guineapig lumbrical has shown that equal MAC multiples of halothane and isoflurane potentiated tubocurarine to a similar extent [18].

The present study has given no support to the view that the different results *in vivo* and *in vitro* might be reconciled by the different effects of the two agents on muscle blood flow. Isoflurane has been reported to increase muscle blood flow [19], and it has been suggested that this might enhance delivery of drugs to the end-plate. The $C_P^{ss}{}_{50}$ defines the steady-state sensitivity of the site of action; access of the drug to the site of action is explicitly modelled by the parameter k_{eo}, which was not affected by the use of a volatile agent. In this respect, the present findings conflict with those of Stanski and colleagues [5], who found that k_{eo} was depressed significantly by 1.0–1.2% halothane (end-tidal), and to a lesser extent by a smaller concentration. The end-tidal concentration of halothane used in our study was at the lower end of the range used by Stanski and colleagues [5], and the effects they noted might have been reproduced here had a greater concentration been used.

The concentrations of volatile anaesthetics used here were smaller than those for which an effect on muscle blood flow was demonstrated by Stevens and others [19], who used 1.2–2.4% isoflurane (end-tidal) for 5 h, or by Eger and others [20], who used 2% halothane (end-tidal). Furthermore, other studies have failed to show an effect of volatile anaesthetic agents on muscle blood flow; thus neither 1.7% halothane (end-tidal) nor 2.6% isoflurane (end-tidal) altered the gastrocnemius muscle blood flow of the dog [21, 22].

The present mean value of k_{eo} (about 0.12 min^{-1}) is similar to the values for other non-depolarizing neuromuscular blocking drugs. Atracurium may undergo spontaneous degradation close to the site of action, and might be expected to have a somewhat greater value of k_{eo} than other drugs; this is not evident in the present results. The rate of spontaneous degradation of atracurium at the end-plate is unknown, but is unlikely to be higher than $k_{\text{non-organ}}$ determined by Fisher and others [23]—about 0.02 min^{-1}. Such a rate would be difficult to detect in the context of an overall value for k_{eo} of 0.12 min^{-1}.

Whereas previous studies have not considered the possible influence of gender, the effect of age on k_{eo} has been assessed previously for atracurium [11] and for vecuronium and pancuronium [12], with negative results. The magnitude of the effect of age on k_{eo} reported here is about 0.001 $\mathrm{min}^{-1}\ \mathrm{yr}^{-1}$, or about 0.03 min^{-1} over three decades. In previous reports, comparisons were made between groups of five or six patients, and for pancuronium a difference between the young and elderly groups rather greater than this was found, which failed to achieve statistical significance. Other groups might have found an effect had they studied a larger number of patients.

It is tempting to relate the influence of age and gender upon k_{eo} to their possible effects upon the circulation. The rate of onset of gallamine-induced neuromuscular block in the dog has been shown to be related directly to muscle blood flow [24]; the present results for k_{eo} might have been obtained, for example, if muscle blood flow declined with advancing age. Such a suggestion must remain speculative, however, because perfusion appeared to have a lesser effect upon recovery [24]. Furthermore, the influence of age and gender upon the microcirculation of the small hand muscles of the human remains unknown.

We have not demonstrated any effect of age, gender or volatile anaesthetic agents on the values of $C_{\mathrm{P}}^{\mathrm{ss}}{}_{\theta}$. Although it shows a tendency to be reduced by the volatile anaesthetic agents, this was not statistically significant; the coefficient of variation of $C_{\mathrm{P}}^{\mathrm{ss}}{}_{\theta}$ in each group was greater than that for $C_{\mathrm{P}}^{\mathrm{ss}}{}_{50}$. It would not be surprising if $C_{\mathrm{P}}^{\mathrm{ss}}{}_{\theta}$ could not be estimated as precisely as $C_{\mathrm{P}}^{\mathrm{ss}}{}_{50}$, which is a median value, whereas $C_{\mathrm{P}}^{\mathrm{ss}}{}_{\theta}$, which represents the steady-state plasma concentration that just fails to block the most sensitive end-plates, reflects the properties of those few end-plates. The relative imprecision of the estimate of $C_{\mathrm{P}}^{\mathrm{ss}}{}_{\theta}$ compared with $C_{\mathrm{P}}^{\mathrm{ss}}{}_{50}$ militates against finding statistically significant effects, should they exist.

The present findings are also negative with regard to the influence of age, gender and anaesthetic agents on γ. The interpretation of this parameter is most difficult; it is also the most sensitive to model specification [14]. It reflects the difference between the steady-state plasma concentrations of atracurium which produce different levels of block, and is thus a function of the dispersion of the sensitivities of the different end-plates within the muscle. It is therefore understandable that it is unaffected by anaesthetic agents, and seems to be independent of age and gender also.

ACKNOWLEDGEMENTS

The equipment required to measure the plasma concentration of atracurium was purchased in part with a grant from the Wellcome Foundation Ltd. We thank Mr A. Dixon for expert technical assistance.

MIDAZOLAM–ALFENTANIL: AN ANAESTHETIC? AN INVESTIGATION USING THE ISOLATED FOREARM TECHNIQUE

I. F. RUSSELL

SUMMARY

Thirty-two women underwent major gynaecological surgery with a midazolam–alfentanil total i.v. anaesthetic regimen. Adequacy of anaesthesia was assessed using a "pressure, rate, sweating and tears" (PRST) scoring system in conjunction with the isolated forearm technique (IFT). The IFT revealed that 72% of patients responded during surgery, but none had spontaneous, unprompted postoperative recall for the event. Three patients, on prompting, provided evidence of recall. The IFT, while indicating which patients are responsive, cannot be used to predict who will have postoperative recall. Lack of explicit postoperative recall does not indicate unconsciousness during surgery. Twenty patients, asked specifically during surgery to indicate the presence or absence of pain, experienced pain at some time during their surgical procedure. The PRST score could not be used to predict when a patient was awake. This low-dose i.v. anaesthetic technique cannot be recommended for general use. (Br. J. Anaesth. 1993; **70**: 42–46)

KEY WORDS

Anaesthetic techniques: total i.v. anaesthesia. Analgesics: alfentanil. Hypnotics, benzodiazepines: midazolam.

A total i.v. anaesthetic technique based on infusions of midazolam and alfentanil has been described [1]; this was associated both with prolonged recovery and a high dependence on naloxone (90%) to establish spontaneous ventilation after operation. A similar technique using smaller doses did not have these drawbacks [2]. In addition to providing haemodynamic stability, this latter technique was claimed also to provide "protection against awareness".

The authors [2] relied on simple postoperative interviews to detect recall for intraoperative events. When an isolated forearm technique (IFT) is used in conjunction with anaesthesia, it is evident that such interviews create a misleading impression regarding the adequacy of general anaesthesia. Even when minimal anaesthesia is used, patients who are awake during surgery rarely remember this [3–6]. Because midazolam has significant amnesic properties, this may reduce further the reliability of postoperative interviews for detecting memory of intraoperative events. The present study using the IFT was initiated to investigate the incidence of wakefulness (intraoperative awareness) [3, 4] and explicit recall (conscious memory for intraoperative events), together with an assessment of the reliability of conventional monitoring in predicting intraoperative awakening when using a similar midazolam–alfentanil i.v. anaesthetic technique.

PATIENTS AND METHODS

The study was approved by the Hospital's Clinical Trials Committee, and informed consent was obtained from women presenting for major gynaecological surgery. The women were informed that a tape recorder would be played to them during surgery and that they would be interviewed twice in the postoperative period with special reference to their perioperative memories. They were given no information on the contents of the tape.

All patients were premedicated with i.m. midazolam 5–10 mg 1.5 h before operation. The doses of drugs used for induction and maintenance of anaesthesia, together with the increments of alfentanil and propofol used in response to signs of light anaesthesia are shown in table I. The anaesthetic technique was a slight modification of that described by Desiderio, Thorne and Shah [2]. Suxamethonium and atracurium were used in place of vecuronium; patients' lungs were ventilated with an air–oxygen mixture (40% oxygen) instead of 100% oxygen; the maintenance infusions were commenced before rather than after induction; the infusions were continued to within 5 min instead of 15 min of the end of surgery; light anaesthesia was indicated by a modified "pressure, rate, sweating and tears" (PRST) [7] score (table II) in conjunction with the isolated forearm technique [6] instead of 20% increases in arterial pressure or heart rate.

The PRST score was assessed every 2 min throughout surgery. The systolic arterial pressure and heart rate were recorded by a non-invasive pressure monitor (Dinamap 845XT, Critikon, Tampa, Florida). A PRST score greater than 2, a response to command or strong reflex activity of the isolated hand were defined as indicative of light anaesthesia.

TABLE III. *An example of the simple questions asked early in the interview to elicit free recall, and the later leading questions used to elicit prompted recall*

Simple questions
I said I would come and ask you some questions:
1. What was the last thing you remember before going to sleep?
2. What was the next thing you remember?
3. Can you remember anything in between?

Leading questions
I said I would play a tape recorder to you during surgery:
1. Do you remember hearing anything?
2. Do you remember hearing anyone talking to you?
3. Do you remember anyone asking you to do anything?
4. Do you remember anyone asking you to do anything with a hand or arm?
5. Do you remember anyone asking you to do anything with your right hand or arm?

Patients' lungs were ventilated with a non-rebreathing circuit at a rate of 10 b.p.m. and a tidal volume of 10 ml kg^{-1}. At the time of the study, capnography was not available.

The prerecorded 1-min, continuous-loop cassette tape used for the IFT contained a 15-s message instructing the patient to open and close the fingers of her right hand. This message was personalized by the inclusion of each patient's preferred first name as follows: "Name, Name. This is Dr Russell speaking. If you can hear me I would like you to open and close the fingers of your right hand, open and close the fingers of your right hand." The tape was started after the patient was connected to the ventilator and was switched off together with the infusions, 5 min from the end of surgery.

Hand movements were categorized as:

Reflex. Movement of the hand or arm which did not conform to the command on the tape.

Unverified response. Any movement of the hand which appeared to conform to the command.

Verified response. An unverified response or persistent reflex type response which was confirmed by direct communication with the patient. Confirmation involved holding the patient's hand and, while raising one of the ear pieces, speaking directly to the patient: "Name, Name, this is Dr Russell speaking. If you can hear me squeeze my fingers".

After a verified response, 20 patients were requested to indicate the presence or absence of pain by appropriately squeezing the investigator's fingers.

After operation, the patients remained in the recovery/extended care area overnight before being transferred to the ward.

The patients were interviewed 1–4 h after operation and again on the third day. The interviews were structured to obtain evidence of dreaming or recall (of the surgical procedure, the taped commands or other spoken commands). The questions posed during the interview (table III), while becoming increasingly leading, did not presuppose any particular answer. At the end of the second interview, patients were asked if they remembered answering these questions before, and if the investigator had been to see them since their operation.

RESULTS

Thirty-three women were investigated (median age 42 yr (range 24–75 yr; upper and lower quartiles 33, 49 yr); median weight 58 kg (range 43–76 kg; upper and lower quartiles 55,64 kg)). One patient was excluded from the final analysis because the conduct of anaesthesia deviated from the design: she had a PRST score greater than 3 which was inadequately treated. This patient responded to command four times, but had no dreams or recall. One other patient received alfentanil 4200 μg (instead of 420 μg) at induction; 12 min later her responses indicated she was awake and in pain; her record has not been excluded.

The surgical procedures included abdominal hysterectomy (22), vaginal hysterectomy (four), other gynaecological laparotomies (five) and pelvic floor repair (one). Median duration of surgery was 60 min (range 28–110 min; upper and lower quartiles 52, 66 min). Two minutes after the induction dose of midazolam, three patients continued to respond to verbal commands and were given propofol to induce

unconsciousness (table IV). After intubation, four patients responded to commands during presurgical preparations. These women all received propofol before surgery started. One of these patients was noted to open her eyes each time her name was used, but as less than 180 s had elapsed since the administration of suxamethonium and no isolating cuff was inflated, there was no movement of the fingers. None of these women had any dreams or recall.

As may be seen from table IV, after induction of anaesthesia only four women completed the procedure without a hand response and 23 of the 32 patients were responsive at some time during "anaesthesia". Table V shows the PRST scores associated with the various responses observed during anaesthesia, and table VI gives an indication of the predictive value of a PRST score of 0. Table VI shows that 48% of the time when a hand response occurred, the PRST score was > 0. When no hand responses occurred, the PRST score was > 0 only 36% of the time (ANOVA, $P < 0.04$). However, 55% of all verified responses occurred with a PRST of 0. The individual patient data in table IV indicate that there was not an excessive contribution to the number of responses from any one patient.

Twenty patients were asked to indicate the presence or absence of pain during surgery. This enquiry was made 39 times and responses indicated comfort on only 10 occasions. All 20 patients experienced pain at some time during surgery.

No patient showed any evidence of recall when interviewed in the recovery room. On the third day, simple questions (table III) appeared to indicate a total lack of recall for events between induction and the time they "awakened" in recovery. However, more detailed leading questions suggested evidence of recall in three women. One was able to paraphrase the instructions given to verify her single response to the taped command. Two other patients were sure they had been asked to do something with their right hand, and while trying unsuccessfully to recall the command, they both demonstrated the appropriate hand movements involuntarily.

Three patients recalled dreaming at some stage. In the recovery room, one patient reported a pleasant dream, either during surgery or immediately after operation, but the other two patients' dreams, reported on the third day, were clearly in the postoperative period. One of these latter patients described a pleasant dream, while the other had two separate nightmares on the second night.

Data were available relating to memory of the early postoperative period for 28 patients. Only four remembered the investigator's recovery room visit (1.5–2 h after surgery).

DISCUSSION

With the exception of different neuromuscular blocking drugs, the modifications to the original anaesthetic technique [2] were intended to increase the doses of midazolam and alfentanil and the sensitivity of clinical monitoring. Consequently, it was disappointing to find that the PRST score lacked any specificity. Individually, or in aggregate, the physiological variables monitored during surgery seemed of little value in predicting the conscious level of patients. Although the greater proportion of responses (48 %) than non-responses (36 %) occurring with a PRST > 0 was significant statistically ($P < 0.04$), this is not clinically useful. Over 51 % of all responses (54 % for verified responses) occurred when the PRST score was zero. Only 13 (8 %) of the responses were associated with a PRST score > 2.

Desiderio, Thorne and Shah [2] administered increments of alfentanil when either arterial pressure or heart rate increased by more than 20 %. The present study using the modified PRST score was intended to enable earlier intervention by allowing supplements of alfentanil with arterial pressure or heart rate increases of only 10 % in association with other signs of light anaesthesia. In reality, sweating and lachrymation were uncommon (except for lachrymation immediately after intubation or when the patient breathed against the ventilator as the effect of the suxamethonium decreased), while arterial pressure and heart rate did not always increase simultaneously. As a result, 20 % increases in arterial pressure or heart rate, occurring in isolation, did not trigger an alfentanil increment. PRST scores of 2 (equivalent to an increase in arterial pressure or heart rate > 20 %), resulting from only one variable, were achieved in 14 patients (two, sweating; one, tears; eight, heart rate changes; three, arterial pressure changes).

It could be argued that these 14 patients exhibited clear clinical signs of light anaesthesia which was treated inadequately and that this was the reason for the high incidence of intraoperative wakefulness. All three patients with evidence of postoperative recall were included in this group. Conversely, only 10 of the 24 patients who responded to intraoperative commands were in this category and, of these, only one responded during this period. Only five of the 22 patients with reflex actions of the isolated hand had a reflex movement at this time.

The first verified response occurred in association with the skin incision on 13 occasions. Assessing "light anaesthesia" at this time was particularly difficult: lachrymation associated with intubation had ceased; arterial pressure and heart rate were either less than normal or were returning quickly to normal after a hypertensive response to intubation. As the effects of the suxamethonium wore off and patients began to make swallowing movements or breathed against the ventilator, it was not unusual for lachrymation to recommence and for arterial pressure, heart rate, or both, to increase. Inflating the tourniquet and administering atracurium abolished all these clinical signs of "light anaesthesia", thus conveying the clinical impression of "adequate anaesthesia". While neither atracurium [8] nor tubocurarine [9] appear to affect cerebration in conscious volunteers, pancuronium [10] is known to reduce the MAC value for halothane. The cause of this is speculative, and both central and peripheral mechanisms are proposed [10]. Perhaps the most plausible is the suggestion that, by abolishing muscle spindle afferent input to the reticular activating system, neuromuscular blockers promote cortical deafferentation; the result of this is that a given concentration of anaesthetic appears more potent. Thus it may be that, by whatever means, neuromuscular blocking drugs do reduce the dose requirements for "true" anaesthetic drugs and, dose for dose, anaesthesia may be "deeper" in the presence of muscle relaxation.

The limitations of conventional monitoring in predicting intraoperative awareness, as seen in this and other studies [5, 6], indicate that considerable caution should be exercised when interpreting the results of studies suggesting evidence for postoperative recall of information presented during "adequate anaesthesia". In the presence of neuromuscular block and in the absence of the IFT, it may not be possible to ensure that a patient is unconscious when the information is presented. In the present study all three women with postoperative evidence of recall responded to the command during "adequate anaesthesia". Likewise, all three dreaming patients responded during surgery.

The results indicate that, on their own or in combination as the PRST score, the clinical criteria used to assess "depth" of anaesthesia are unreliable and could not be relied on to predict the presence or absence of consciousness during anaesthesia. When using this anaesthetic without the IFT, it is impossible for the anaesthetist to know whether or not a patient is awake.

If the aim of general anaesthesia is to ensure that a patient has no recognizable conscious recall of surgery and views the perioperative period as a "positive" experience then, as suggested [2], this midazolam–alfentanil infusion regimen may fulfil that requirement. However, the definition of general anaesthesia would normally include unconsciousness and freedom from pain during surgery—factors not guaranteed by this technique. In the majority of patients in the present study, the state of mind produced by this low dose midazolam–alfentanil regimen could not be viewed as "general anaesthesia", but rather it should be regarded as "general amnesia".

EFFECTS OF ETOMIDATE ON THE ADRENOCORTICAL AND METABOLIC ADAPTATION OF THE NEONATE

T. A. CROZIER, C. FLAMM, C. P. SPEER, W. RATH, W. WUTTKE, W. KUHN AND D. KETTLER

SUMMARY

The effects of etomidate on corticosteroid synthesis were compared with those of methohexitone. We studied 40 neonates, 22 delivered by elective and 18 by emergency Caesarean section. Apgar scores, blood sugar and plasma concentrations of cortisol and etomidate were evaluated at birth and 2 and 6 h postpartum. There was no difference in Apgar scores attributable to the induction agent. The median cortisol concentrations in cord blood were small (136 nmol litre^{-1}; range 47–478 nmol litre^{-1}, and 259 nmol litre^{-1}; range 58–1504 nmol litre^{-1} after elective and emergency sections, respectively). During the study, cortisol concentrations increased in the infants in the methohexitone groups and decreased in those in the etomidate groups; this effect was most evident 2 h after delivery (methohexitone groups 245 nmol litre^{-1}, range 70–959 nmol litre^{-1}; etomidate groups 121 nmol litre^{-1}, range 56–320 nmol litre^{-1}). There was no difference at 6 h postpartum (methohexitone groups 183 nmol litre^{-1}, range 25–756 nmol litre^{-1}; etomidate groups 190 nmol litre^{-1}, range 33–628 nmol litre^{-1}). The concentration changes during the study period differed significantly ($P <$ *0.005) with respect to the induction agent. Blood glucose concentrations were small (mean (SD) in all 40 neonates 2 h postpartum was 2.64 (0.77) mmol litre^{-1}), and did not differ between the groups. There were 17 cases of moderate to severe hypoglycaemia (blood glucose concentrations less than 2.5 mmol litre^{-1}): nine in the etomidate group and eight in the methohexitone group. Mean (SD) fetal: maternal etomidate concentration ratio was 0.48 (0.27) with an umbilical arterial etomidate concentration of 83 (39) ng ml^{-1} (340 (160) nmol litre^{-1}). The concentration was 9.3 (42) ng ml^{-1} (38.0 (22) nmol litre^{-1}) at 2 h and 6 (2.9) ng ml^{-1} (24.6–15 nmol litre^{-1}) at 6 h.* (Br. J. Anaesth. 1993; **70**: 47–53)

KEY WORDS

Anaesthesia: obstetric. Anaesthetics, intravenous: etomidate, methohexitone. Hormones: corticosteroid synthesis. Metabolism: neonatal.

In Western Europe and North America an increasing percentage of newborn children are delivered by Caesarean section and the immediate postpartum condition of the neonate is influenced by the anaesthetic induction agent [1]. The drugs used most commonly are the barbiturates, methohexitone and thiopentone, both of which have similar effects on the neonate [2]. The less frequently used induction agent, etomidate, compares favourably with thiopentone with regard to Apgar scores and the time to sustained spontaneous ventrilation [3].

Etomidate is therefore an alternative induction agent for those patients for whom barbiturates are undesirable (e.g. those with asthma, porphyria, allergy, heart disease). However, etomidate inhibits cortisol synthesis in the adrenal cortex of adults [4, 5], and whilst this probably applies also to neonates, the available data are scarce [6]. Cortisol, glucagon and catecholamines are required for adaptation to extrauterine life in order to maintain a continuous supply of glucose by gluconeogenesis and glycolysis. The circulating plasma concentrations of cortisol are typically smaller in infants delivered by elective Caesarean section than in those after vaginal delivery [7, 8], and a further reduction of cortisol synthesis might therefore impair the adaptive capacity of the infant and lead to an increased incidence of hypoglycaemia [9].

This study was conducted to determine to what extent etomidate, given to the mother for induction of anaesthesia for Caesarean section, affected concentrations of plasma cortisol and blood glucose in the neonate.

PATIENTS AND METHODS

We studied 40 neonates delivered by Caesarean section under general anaesthesia. The study was approved by the Human Ethics Commission of the Medical Faculty of the University of Göttingen, and informed consent was obtained from the mothers. All patients were monitored during the final hours of

pregnancy by continuous cardiotocography. One group consisted of 22 parturients undergoing elective Caesarean section because of abnormal fetal presentation, previous Caesarean section or documented placenta praevia. None of these patients was in labour, and none had cardiotocographic signs of fetal distress. In the second group there were 18 parturients in labour in whom Caesarean section was performed as an emergency measure because of signs of severe intrauterine fetal distress, such as pathological heart rate deceleration patterns. In each of the two groups the parturients were allocated randomly to receive either methohexitone or etomidate for induction of anaesthesia. Exclusion criteria were diabetes mellitus, eclampsia, recent corticosteroid treatment and known allergy to either etomidate or methohexitone.

Patients were placed on the operating table in a head-up, left lateral position. While the patient was being prepared for surgery, indwelling cannulae were placed in peripheral veins, 500 ml of balanced salt solution was infused i.v., precordial ECG leads were attached and the patient's lungs were preoxygenated for at least 5 min with 100 % oxygen via a face mask. When the obstetricians were prepared for incision, pancuronium 1–1.5 mg was injected i.v. [10, 11] and, as soon as the patient noticed an effect, anaesthesia was induced with a rapid sequence technique using either methohexitone 1 mg kg^{-1} or etomidate 0.4 mg kg^{-1}, followed immediately by suxamethonium 1.5 mg kg^{-1}. Cricoid pressure was applied as soon as the patient lost consciousness and the trachea was intubated within 30 s in all patients. The operation began immediately after the tracheal tube was positioned correctly. The lungs were ventilated with 50 % nitrous oxide in oxygen until the uterus was incised, at which time the gas mixture was changed to 100 % oxygen. Volatile anaesthetics were not added until the umbilical cord was severed, as routine incision-to-delivery time is very short in our institution (< 5 min). After the umbilical cord was clamped, the rest of the operative procedure was conducted under balanced anaesthesia with fentanyl 0.1–0.2 mg, 66 % nitrous oxide and 0.5–1.5 % halothane in oxygen, with pancuronium if necessary. Routine intraoperative monitoring consisted of continuous ECG and arterial pressure, pulse oximetry and capnometry.

The neonates were placed under a radiation heater and cared for by a paediatrician who also performed the Apgar scoring, but who was unaware of the induction drug. The infants were then transferred either to the nursery ward, or to the paediatric intensive care unit if they were markedly distressed or had a birth weight less than 2.5 kg. In our institution, Caesarean section neonates are normally not fed until 6 h postpartum. However, if the results of the first blood sugar determination at 2 h postpartum revealed a value < 1.4 mmol $litre^{-1}$ (25 mg dl^{-1}), the children were fed a small amount of sweetened tea.

Blood samples for cortisol and etomidate were obtained in EDTA-coated tubes, centrifuged immediately, and the plasma was stored at –80 °C until required for assay. Maternal venous samples were taken from the arm contralateral to that used for drug administration before induction of anaesthesia, simultaneously with umbilical cord clamping, and 2 and 6 h postpartum. The initial neonatal sample was obtained from the umbilical artery. The samples at 2 and 6 h postpartum were capillary samples from the heel. Blood sugar measurements at 2 and 6 h postpartum were performed by the hospital laboratory using an automated analyser.

Cortisol measurements were performed in duplicate with a commercially available radioimmunoassay kit (Labordiagnostika Gödecke, Freiburg, West Germany). The antibody is highly specific with a cross-reactivity of only 3.4 % with 11-deoxycortisol and less than 1 % with other steroid hormones. The sensitivity of the assay is 5.5 nmol $litre^{-1}$ (0.2 μg dl^{-1}) with an intra-assay coefficient of variation of 2.2 %. Normal (SD) morning values in our laboratory for adults are 417 (111) nmol $litre^{-1}$ (15 (4) μg dl^{-1}).

Etomidate concentrations were measured by gas chromatography using nitrogen detection with the method described by De Baer, Smeekens and Breimer [12]. The assay has a limit of sensitivity of 2.5 ng ml^{-1} (10 nmol $litre^{-1}$), and coefficients of variation of 6 % at a concentration of 244 ng ml^{-1} (1000 nmol $litre^{-1}$) and 11 % at a concentration of 24.4 ng ml^{-1} (100 nmol $litre^{-1}$).

Statistical analysis

The following hypotheses regarding circulating concentrations of cortisol and glucose were tested: greater plasma concentrations of cortisol are found in neonates delivered by emergency Caesarean section compared with those delivered by elective section; neonatal plasma cortisol concentrations are reduced by etomidate compared with methohexitone; postpartum blood glucose concentrations are smaller in neonates exposed to etomidate than those exposed to methohexitone; etomidate decreases maternal plasma cortisol concentrations. No assumptions were made as to the distribution of the cortisol concentration data in the population of neonates investigated, and they were therefore analysed by the non-parametric Mann–Whitney *U* test or the Kruskal–Wallis test. Confidence intervals for the differences between medians were calculated by the method described by Moses [13]. Blood glucose concentrations were found to be normally distributed, and these data and the patient data were analysed by ANOVA.

RESULTS

There was no significant difference between the groups in maternal age or weight, gestational age, incision to delivery time, amount of etomidate administered or duration of surgery. There was no difference in the induction agent subgroups in birth weight or Apgar score. However, although the gestational age was the same in all groups, the neonates in the emergency Caesarean section group had smaller birth weights and their 1- and 5-min Apgar scores were less than those in the elective Caesarean group (tables I, II).

Plasma cortisol concentrations

The plasma cortisol concentrations in the neonates delivered by elective Caesarean section were in the low normal range, and the median cortisol concentrations in the cord blood of infants delivered by emergency Caesarean section were slightly greater (table III). The median plasma cortisol concentration over the entire 6-h study period was significantly greater ($P < 0.05$) in neonates delivered by emergency Caesarean section (189 nmol litre^{-1}, range 33–1504 nmol litre^{-1}) than in those after elective section (130 nmol litre^{-1}, range 25–756 nmol litre^{-1}).

During the postpartum observation period, median cortisol concentrations in the neonates exposed to etomidate decreased, whereas those in the infants in the methohexitone groups increased. This effect was most obvious at 2 h postpartum. The median change in plasma cortisol concentrations during the entire 6-h study period was an increase in the methohexitone groups of 58 nmol litre^{-1} (range −250 to 617), and a decrease in the etomidate groups of 56 nmol litre^{-1} (range −1415 to 570) ($P < 0.005$).

TABLE IV. *Median [range] maternal plasma cortisol concentrations and † 95% confidence limits for the difference between drug medians (methohexitone – etomidate). Group 1 = Elective Caesarean section; group 2 = emergency section. The reduction in plasma cortisol concentrations at 2 h postpartum attributable to the effects of etomidate was statistically significant* (P = 0.005).

6 h postpartum	2.58 (0.53) [1.79–3.08]	3.04 (0.95) [1.68–4.54]	2.73 (0.60) [1.9–3.86]	2.55 (0.37) [1.96–3.14]
Neonates with hypoglycaemia				
Severe (glucose < 1.4 mmol litre^{-1})	4 of 11	1 of 11	1 of 9	2 of 9
Moderate (glucose 1.4–2.5 mmol litre^{-1})	1 of 11	3 of 11	3 of 9	2 of 9
Clinical signs	3 of 11	3 of 11	1 of 9	2 of 9

The 95% confidence limits for the difference show that the median cortisol concentration in the etomidate groups was 61–267 nmol litre^{-1} less than the median in the methohexitone groups.

All parturients had increased preoperative plasma cortisol concentrations which had not changed appreciably at the time of umbilical clamping (table IV). The median plasma cortisol concentration in the methohexitone group was 1376 nmol litre^{-1} (range 917–2029 nmol litre^{-1}) and in the etomidate group 1164 nmol litre^{-1} (range 639–1918 nmol litre^{-1}). At 2 h postpartum (approximately 1 h after the end of surgery) plasma cortisol concentrations in the methohexitone groups had not changed significantly (median change from the time of umbilical clamping, –33 nmol litre^{-1} (range –809 to 562 nmol litre^{-1})), whereas plasma cortisol concentrations in the etomidate groups exhibited a median decrease of 474 nmol litre^{-1} (range –920 to –42). The median concentration in the etomidate groups was 300–865 nmol litre^{-1} smaller than that in the methohexitone groups (95% confidence limits) ($P < 0.005$). There was no difference between the groups at 6 h postpartum (table IV), at which time the median cortisol concentration in the methohexitone groups was 817 nmol litre^{-1} (range 334–2029 nmol litre^{-1}) and that in the etomidate groups 669 nmol litre^{-1} (range 361–1502 nmol litre^{-1}).

Neonatal blood glucose

Mean blood glucose concentrations were in the low normal range of approximately 2.6–2.7 mmol litre^{-1}. The smallest individual blood glucose concentrations were found in neonates in the methohexitone groups. There was no significant differences between the blood glucose concentrations in the four groups at any time and there were no significant changes in blood glucose concentrations during the study (table V). Mean (SD) blood glucose concentration was 2.72 (0.82) mmol litre^{-1} for the 20 neonates in the methohexitone groups and 2.55 (0.77) mmol litre^{-1} for those in the etomidate groups.

In our institution a neonatal blood glucose concentration < 1.4 mmol litre^{-1} is defined as severe hypoglycaemia requiring glucose. Moderate hypoglycaemia with concentrations between 1.4 and 2.5 mmol litre^{-1} is regarded as a transient phenomenon which only requires close monitoring. At 2 h postpartum, nine of 20 neonates exposed to etomidate had developed hypoglycaemia; five cases were classified as severe. Compared with this, eight of the 20 infants delivered by Caesarean section induced with methohexitone developed hypoglycaemia, three severe. The 95% confidence limits for the difference between the means of the two groups show that the blood glucose concentrations could be 0.349 mmol

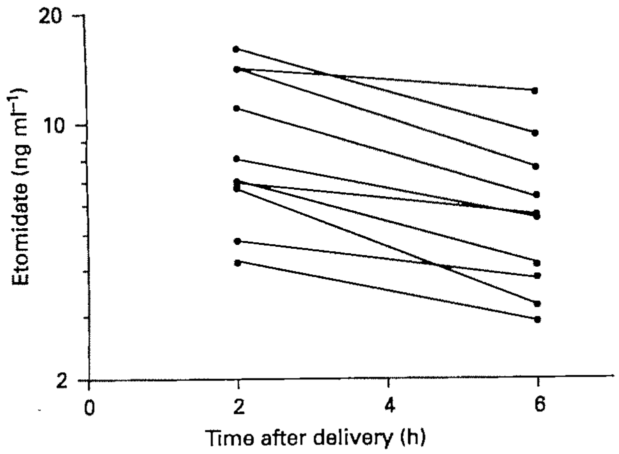

FIG. 1. Plasma concentrations of etomidate in 10 neonates at 2 and 6 h after delivery.

litre^{-1} less or 0.014 mmol litre^{-1} greater in the neonates exposed to etomidate compared with those given methohexitone.

Four of the five infants in the etomidate group with severe hypoglycaemia exhibited clinical symptoms such as irritability, while one did not. All three infants from the methohexitone group with extremely small blood glucose concentrations showed clinical signs of hypoglycaemia, as did two others who had normal blood glucose concentrations (table V). Although the neonates delivered by emergency Caesarean section had markedly smaller birth weights, they had neither smaller median blood glucose concentrations nor a greater incidence of hypoglycaemia.

Etomidate concentrations

Etomidate plasma concentrations were measured in 10 of the newborn infants (five each from the elective and the emergency section groups). Mean (SD) etomidate concentration in umbilical arterial blood was 83 (39) ng ml^{-1} (340 (160) nmol litre^{-1}) with a range of 42–154 ng ml^{-1} (172–631 nmol litre^{-1}), while the mean concentration in maternal plasma at the time of cord clamping was 198 (79) ng ml^{-1} (811 (324) nmol litre^{-1}) with a range of 77–352 ng ml^{-1} (316–1443 nmol litre^{-1}). Mean fetal-to-maternal etomidate concentration ratio (umbilical arterial: maternal venous (UA:MV)) was thus 0.48 (0.27). Mean etomidate concentration was 9.3 (4.2) ng ml^{-1} (38 (22) nmol litre^{-1}) 2 h after delivery and 6 (2.9) ng ml^{-1} (24.6 (15) nmol litre^{-1}) at 6 h postpartum. Figure 1 shows the temporal changes of the etomidate concentrations in each individual child.

DISCUSSION

We have shown that etomidate had a transient depressant effect on plasma cortisol concentrations in neonates, especially in infants subjected to intrauterine distress. Metabolic consequences of this impairment were not detected.

The choice of induction agent and its dose is of well-documented importance for the postpartum condition of the neonate delivered by Caesarean section [1, 2, 14, 15]. Thiopentone, methohexitone and etomidate are equally suitable for this purpose, and the last of these is an alternative for parturients for whom barbiturates are contraindicated [3]. However, etomidate inhibits cortisol synthesis in the adrenal cortex. The disturbing aspect of this fact is that circumstantial and experimental evidence shows a connection between inhibited corticosteroid synthesis and increased mortality in intensive care patients [16] and animals [17]. Although the neonate resembles neither the intensive care patient nor the animal model, it does represent a unique situation in mammalian life, insofar as the newborn infant has just undergone the transition from a state of continuous i.v. nutrition via the placenta to one characterized by intermittent enteral feeding. It must therefore be capable of adapting its metabolism to the maintenance of relatively constant blood sugar concentrations during periods of starvation by means of glycogenolysis and gluconeogenesis. In the immediate postpartum period this is accomplished by a surge of glucagon secretion which stimulates glycogenolysis [18]. Further starvation necessitates the actions of cortisol and catecholamines to stimulate gluconeogenesis. It is in this context that the extent and duration of corticosteroid synthesis inhibition in the newborn is important.

The plasma cortisol concentrations in the cord blood of our neonates after elective Caesarean section were very similar to those described previously [6, 7, 19]. The cortisol concentrations in the infants of our study delivered by emergency Caesarean section were slightly greater, and in a range comparable to values reported earlier [7, 20]. We also observed a slight increase 2 h postpartum in the infants whose mothers had been given methohexitone, in both the elective and the emergency groups. A similar increase has been described [6, 19], indicating that this is probably a typical occurrence after Caesarean section. Reddy, Pizer and Bull [6] attributed this increase to the decreasing influence of maternal oestrogen on fetal cortisol synthesis, but we believe that it is equally likely that it reflects the demands placed on intermediate metabolism for maintaining stable glucose concentrations.

The plasma cortisol concentrations were smaller in the infants whose mothers had been given etomidate compared with those receiving methohexitone. This significant difference may be attributed to the effect of etomidate which not only obtunded the increase observed in the methohexitone groups, but also caused concentrations to decrease. There was a reduction of more than 50% in the etomidate group at 2 h after delivery in neonates who had suffered intrauterine distress and had been delivered by emergency section. These results confirm the findings of Reddy, Pizer and Bull [6] that etomidate affects cortisol secretion in term neonates. Our results are an extension of their observations in that they show that the effect of etomidate on adrenal cortisol synthesis can no longer be detected in unstressed neonates 2 h after delivery. However, the effect of etomidate may be present at this time as, in stressed infants after emergency section, it was still demonstrable 2 h postpartum. Six hours is a reasonable estimate of the maximum duration of the inhibitory effects of etomidate in this setting. This agrees with the results of previous studies in adults [21].

The increased preoperative maternal cortisol concentrations may be interpreted as evidence of an increased activity of the pituitary–adrenal axis. This is in accordance with the increased ACTH, β-endorphin and cortisol concentrations described previously in parturients [20, 22]. The administration of etomidate was associated with a perioperative decrease in maternal plasma cortisol concentrations, while methohexitone had no such effect: At 2 h postpartum, the difference between the two groups was statistically significant, but it was no longer evident after 6 h. This is also in agreement with our data in adults [5].

The small blood concentrations of glucose observed 2 h after birth, irrespective of the induction agent, the indication for the Caesarean section or the birth weight, reflect the fact that Caesarean section neonates are subjected to only minor stress during delivery. As a result, moderate to severe hypoglycaemia was fairly frequent in all groups. There were insufficient data to allow the detection of any significant difference in the incidence. We consider that the most important clinical conclusion from these data would be to feed all Caesarean section neonates much earlier than is customary in our institution.

The minimum hypnotic plasma concentration of etomidate is approximately 250–300 ng ml^{-1} in adults [23]. Although there is no information on the hypnotic threshold concentrations in neonates, the etomidate concentrations in cord blood were considerably less than this in all infants. This is in agreement with the clinical assessment of the children, who were all quite awake and lively. The etomidate concentration data at birth are in good agreement with those reported by Gregory and Davidson (24), who found mean (SD) maternal concentrations of 198.8 (73.9) ng ml^{-1} and umbilical arterial concentrations of 62.9 (33.3) ng ml^{-1} using a slightly less sensitive etomidate assay with similar precision. The smaller neonatal concentrations in their study may be attributable to the fact that incision-to-delivery times were two to four times longer than in the present study. The etomidate concentrations at delivery were definitely greater than the 110 nmol litre^{-1} (27 ng ml^{-1}) at which there is a 50% inhibition of cortisol synthesis in adults [21]. At 2 h postpartum, the umbilical arterial etomidate concentrations had decreased to less than this in all of the infants, and at 6 h only three neonates had an etomidate plasma concentration greater than the minimum effective value of 20 nmol litre^{-1}. The neonatal plasma etomidate concentrations are not amenable to formal kinetic analysis; however, the mean concentration decreased by about 40% from the 2nd to the 6th hour. This approximate half-life of 6 h is comparable to that reported by de Ruiter and colleagues [25] in surgical patients, although longer than the half-life observed by Schüttler and colleagues [26] in adult volunteers.

We have shown that the clinical condition of neonates delivered by Caesarean section was comparable after induction of general anaesthesia with either etomidate or methohexitone. Etomidate did cause a suppression of plasma cortisol concentrations in neonates, but the effect is only transient. The inhibited cortisol synthesis was not associated with a marked disturbance of glucose homeostasis; but the data were insufficient to decide if it caused a significantly increased incidence of hypoglycaemia. We conclude that there is no evidence that would preclude the use of etomidate for induction of anaesthesia for Caesarean section. However, we would recommend early feeding for all infants delivered by Caesarean section, regardless of the anaesthetic given in order to avoid hypoglycaemia.

NITROUS OXIDE-MEDIATED ACTIVATION OF THE EEG DURING ISOFLURANE ANAESTHESIA IN PATIENTS

A. YLI-HANKALA, L. LINDGREN, T. PORKKALA AND V. JÄNTTI

SUMMARY

We have studied the effects of nitrous oxide on EEG burst suppression patterns during stable isoflurane anaesthesia in 13 ASA I patients. After induction of anaesthesia with propofol, the concentration of isoflurane was increased with continuous EEG monitoring to burst suppression level (mean end-tidal concentration of isoflurane, 1.7 (SD 0.2) %), and kept constant during the study. During surgery, isoflurane in air and oxygen ($F_{I_{O_2}}$ 0.35), or isoflurane in 65% nitrous oxide in oxygen were given to each patient for 30 min, in random order. EEG was recorded and digitized off-line. The proportion of EEG suppression time was measured after a washin or washout period of at least 15 min for nitrous oxide. There was a significant decrease in the proportion of EEG suppression time (from 69.5 to 43.7%) when air was replaced by nitrous oxide. We conclude that the EEG effects of isoflurane and nitrous oxide are not additive and that nitrous oxide opposes the depression of isoflurane on the central nervous system. (Br. J. Anaesth. 1993; **70**: 54–57)

KEY WORDS

Anaesthetic techniques: inhalation. Anaesthetics, gases: nitrous oxide. Anaesthetics, volatile: isoflurane. Brain: electroencephalography.

The effects of nitrous oxide on the electroencephalogram (EEG) during inhalation anaesthesia have been studied extensively. In a study using spectral analysis [1], there were no changes in the EEG from nitrous oxide when it was used in combination with other anaesthetics. Other studies, however, have reported a reduction of total EEG spectral power [2], or an increase in fast frequency EEG power bands [3] when inhalation anaesthesia was supplemented with nitrous oxide.

At 1.5–2.0 minimal alveolar concentration (MAC) of isoflurane anaesthesia, the EEG shows a burst suppression pattern—relatively silent EEG periods interrupted by high amplitude bursts [4]—which appear synchronously in the whole cortex [5]. When anaesthesia is deepened further, duration of suppressions increases and, finally, an isoelectric EEG results [4]. We have demonstrated that nitrous oxide slows the rhythm of EEG activity during isoflurane anaesthesia in man, without appearance of an EEG burst suppression pattern, when 1.5% end-tidal isoflurane anaesthesia is deepened with 65% nitrous oxide [6]. Recent animal studies have demonstrated the activation of EEG by nitrous oxide during burst suppression isoflurane anaesthesia [7, 8]. Rampil and colleagues have reported that nitrous oxide activates EEG during desflurane burst suppression anaesthesia in volunteers [9]. The effect of nitrous oxide on isoflurane burst suppression has not, however, been studied in humans. Therefore, we studied the effect of nitrous oxide on the EEG burst suppression pattern during isoflurane anaesthesia and surgery in healthy patients.

PATIENTS AND METHODS

The study was approved by the Ethics Committee of Helsinki University Central Hospital. Thirteen healthy ASA I patients (table I) gave informed consent.

Anaesthesia

Patients were premedicated with oral diazepam 0.2 mg kg^{-1} 90 min before induction of anaesthesia with propofol (mean) 1.8 (SD 0.2) mg kg^{-1} i.v. Vecuronium was given for neuromuscular block and no anticholinergic agent was used. Positive pressure ventilation was performed via a tracheal tube, using a Servo respirator (Siemens–Elema, Sweden). Tidal volume was adjusted to maintain normocapnia (end-tidal carbon dioxide 5.0 kPa), measured with a Datex Capnomac monitor (Instrumentarium Ltd, Fin-

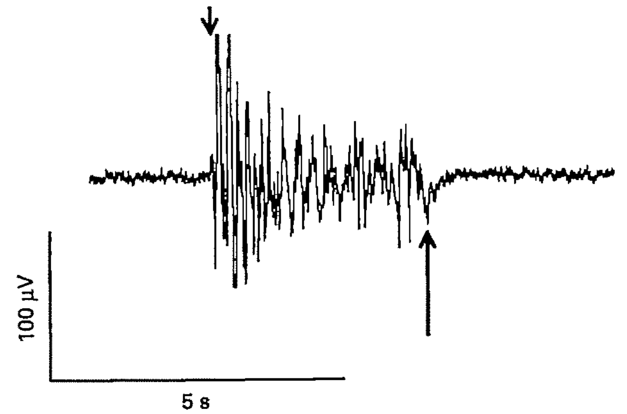

FIG. 1. Definition of the beginning of EEG burst and suppression. Burst onset at the short, down-pointing arrow. Suppression onset at the long, up-pointing arrow. Note the EEG notch at the beginning of suppression.

land). Arterial pressures were measured non-invasively with a Datex Normocap monitor at intervals of 3 min. Temperature was measured from the nasopharynx and normothermia was maintained using warming blankets. All patients were horizontal and supine during the study.

At first, isoflurane was delivered with oxygen in air ($F\mathrm{I}_{\mathrm{O}_2}$ 0.35). Isoflurane concentrations were monitored on-line (Datex Capnomac). For each patient, the analyser was calibrated with a known concentration of isoflurane and carbon dioxide, and at 0%.

All the recordings were performed during the surgical procedure. After induction of anaesthesia, we waited 45 min to allow the effect of propofol to disappear. EEG was monitored continuously. Anaesthesia was deepened gradually to a point at which burst suppression occurred on the EEG (1.7 (0.2)% end-tidal isoflurane), and then kept constant during the study.

During two 30-min periods, isoflurane in air and oxygen ($F\mathrm{I}_{\mathrm{O}_2}$ 0.35), and isoflurane and 65% nitrous oxide in oxygen ($F\mathrm{I}_{\mathrm{O}_2}$ 0.35) was delivered to each patient. The initial gas mixture was selected at random. In seven patients, air and oxygen were given before challenge with nitrous oxide and oxygen, while the other patients received nitrous oxide and oxygen first. Analyses were performed on EEG data recorded after a washin or washout period of 15 min for nitrous oxide.

Signal recording and analysis

Silver–silver chloride dome EEG electrodes were placed in C_z and F_z positions (International 10–20 System). EEG was amplified and monitored with Datex ABM monitor (Instrumentarium, Finland, bandwidth 1.5–25 Hz (−3 dB)) and recorded on tape (Racal FM tape recorder, Racal, England). Event marks, such as turning on/off nitrous oxide, also were recorded on tape.

EEG and event mark signals were digitized off-line at 200 samples s^{-1} per channel to a PC-compatible microcomputer. EEG burst–onset points and suppression-onset points were selected manually with a cursor on the computer screen. This selection was always performed by one of the authors (T.P.) unaware of the order of randomization. End-point of the burst was defined as the EEG notch, which is seen at the beginning of suppression (fig. 1).

As the recordings were made during routine surgical procedures, artefacts occurred randomly in the signal. Only bursts and suppressions completely devoid of artefact were included in the analysis. Recordings were analysed for duration of suppression, which was expressed as percentage of the sum of artefact-free bursts and suppressions in a 15-min period.

Statistics

Data were analysed using the computer software program BMDP (University of California, Berkeley, U.S.A.). The comparisons were tested with Wilcoxon's matched-pairs signed-ranks test. The data are given as mean (SD). $P < 0.05$ was considered statistically significant.

RESULTS

The duration of EEG bursts and suppressions occurring in one patient is presented in figure 2. In the study group, the proportion of EEG suppression

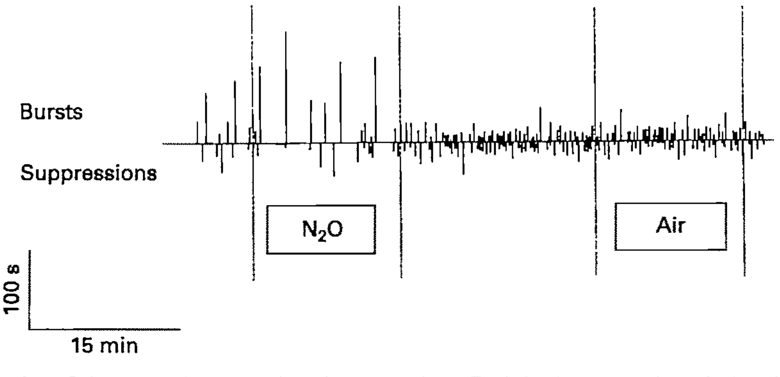

FIG. 2. Duration of EEG bursts and suppressions in one patient. Both horizontal and vertical scales present time. Horizontal line = baseline. Bursts are presented as lines upwards, suppressions as down-pointing lines from the baseline. The long dotted vertical lines delimit the two EEG analysis periods. N_2O = EEG analysis period during isoflurane–nitrous oxide–oxygen anaesthesia. Air = EEG analysis period during isoflurane–air–oxygen anaesthesia. The proportion of EEG suppression time was evaluated during nitrous oxide inhalation and after a wash-out period of 20 min for nitrous oxide. Note the rapid reduction in the duration of EEG bursts, when nitrous oxide exposure was replaced by air at the end of the first analysis period.

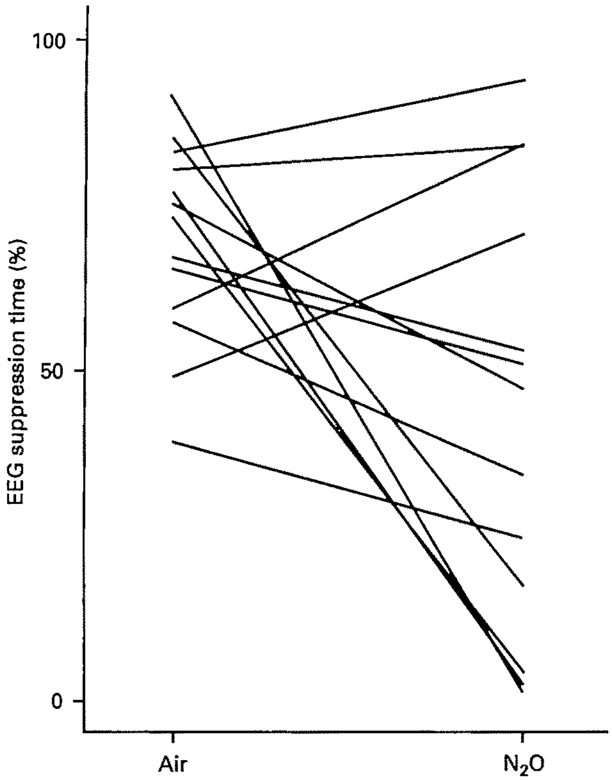

FIG. 3. Proportion of EEG suppression time in 13 patients during isoflurane in air (Air) and during isoflurane in nitrous oxide (N_2O) analysis period. Each line represents one individual. The initial gas mixture (air or nitrous oxide) was selected at random.

time was 69.5 (15.1) % during isoflurane–air–oxygen anaesthesia. This proportion decreased to 43.7 (33.1) % during isoflurane–nitrous oxide–oxygen anaesthesia ($P < 0.05$) (fig. 3). Mean length of EEG bursts changed from 10 (7) s to 24.8 (28) s ($P < 0.01$), and that of EEG suppressions from 22.7 (13) s to 20.8 (23) s (ns), when air was replaced by nitrous oxide.

The course of surgery was uneventful and without major bleeding in all patients. Mean arterial pressure and heart rate at the end of isoflurane–air–oxygen recording period were 73 (18) mm Hg and 82 (13) beat min^{-1}, respectively. The same figures at the end of nitrous oxide inhalation were 70 (16) mm Hg and 76 (13) beat min^{-1}, respectively (ns).

DISCUSSION

The present study shows that, when burst suppression isoflurane anaesthesia was supplemented by 65 % nitrous oxide, the duration of EEG suppression decreased and the duration of bursts increased—that is, nitrous oxide activated the EEG during burst suppression.

The activation of isoflurane EEG by nitrous oxide, with [7] or without [8] changes in cerebral blood flow (CBF), has been demonstrated in animals. In their recent study in patients, Algotsson and colleagues [10] reported an increase in CBF, with a decrease in cerebral vascular resistance and an activation pattern in the EEG when 1.7 % isoflurane–air was replaced by 0.85 % isoflurane–nitrous oxide–oxygen. However, the EEG was not studied during constant concentrations of isoflurane. The present result, with constant isoflurane concentrations, is in accordance with our earlier study [6] showing that, although the frequency of EEG rhythm decreased when 65 % nitrous oxide was added to 1.5 % isoflurane anaesthesia, EEG suppressions were not seen. In the present study, addition of 0.7 % (0.6 MAC) isoflurane instead of nitrous oxide, would probably have produced continuous EEG suppression in most of our patients [4].

The mechanism of activation of the EEG by nitrous oxide is interesting. Algotsson and colleagues [10] proposed a secondary effect of nitrous oxide on the brainstem reticular centres, which could also explain the result obtained in our study.

Four of our 13 patients showed an increase in the duration of EEG suppression during nitrous oxide. In two of these subjects the operation was abdominal, while in the two others it was breast surgery. The level of surgical stimulation in intra-abdominal surgery may differ from that of breast surgery. The type of surgery, however, seemed not to have any influence on the results.

Previous human studies on the effect of nitrous oxide on the EEG have often applied spectral analysis [1–3, 6]. Some of these results may also be interpreted as nitrous oxide-induced activation of the EEG. Spectral analysis is, however, sensitive to the bandpass characteristics of the recording system [11]. Furthermore, in addition to the spectral content of EEG, changes may occur in the topographical distribution and waveform of the EEG. This was demonstrated in our earlier study [6] which gave controversial results: nitrous oxide slowed the rhythm of EEG activity during isoflurane anaesthesia. Visual inspection of the raw EEG signal, however, showed that this was caused by frontal rhythmic delta activity, which may be interpreted as lightening of anaesthesia [12]. The waveform of the raw EEG signal, and transients (spikes, short suppressions), are lost in transformation to the power spectrum. Moreover, power spectrum analysis assumes a stationary signal, which is not present during burst suppression. Time domain analysis of EEG is thus more suitable for burst suppression EEG studies.

We used propofol for induction of anaesthesia. Propofol is claimed to have an effect on the EEG for only about 10 min after induction [13]. In our study, 45 min elapsed from administration of propofol to the recordings. Thus it is unlikely that propofol had any effect on the EEG during our measurements.

The burst involves d.c. shift in the EEG, which could be seen with increased bandwidth—a longer time constant in recording [14]. Usually, because of the high-pass filter, this d.c. shift is seen only as a small notch in the end of the burst. We used that notch as the definition of the suppression onset point, as it marks the end of the burst, which otherwise is difficult to determine.

In conclusion, we have shown that, during isoflurane burst suppression, nitrous oxide activated the EEG. The effect of nitrous oxide should be taken into consideration when isoflurane burst suppression is used as an indicator for depth of anaesthesia.

ACKNOWLEDGEMENTS

This study was supported by a grant from the Academy of Finland.

COMPARISON OF THORACIC ELECTRICAL BIOIMPEDANCE AND THERMODILUTION FOR THE MEASUREMENT OF CARDIAC INDEX IN PATIENTS WITH SEVERE SEPSIS

J. D. YOUNG AND P. McQUILLAN

SUMMARY

Cardiac index was measured using thoracic bioimpedance (CIbi) and thermodilution (CItd) in 19 patients with proven sepsis, undergoing artificial ventilation of the lungs. There was a poor correlation between the techniques ($r = 0.36$, 242 data sets, regression line CIbi = 0.16 CItd + 2.56 litre min^{-1} m^{-2}). The overall bias (CItd–CIbi) was 1.69 litre min^{-1} m^{-2} with limits of agreement (precision) of +4.17 to −0.79 litre min^{-1} m^{-2}. In individual patients the bias was from −0.46 to 4.56 litre min^{-1} m^{-2} with the limits of agreement from ±0.29 to ±2.55 litre min^{-1} m^{-2} around the bias values. The two techniques cannot be used interchangeably in this group of patients. (Br. J. Anaesth. 1993; **70**: 58–62)

KEY WORDS

Complications: sepsis. Measurement techniques: thermodilution, thoracic bioimpedance. Monitoring: cardiac index.

Variations in the electrical impedance of the thorax to an alternating current (Z) which occur synchronously with the cardiac cycle were observed nearly 40 years ago [1]. The first use of this phenomenon to measure stroke volume and cardiac output was described by Nyboer [2] and developed by Kubicek and colleagues [3, 4]. The method uses the maximum rate of change of thoracic bioimpedance, ($\delta Z/\delta t$max) during systole to calculate stroke volume. The original equation used by Kubicek and colleagues was modified by Bernstein [5] to remove assumptions about body morphology. This equation is used to calculate stroke volume in a commercially available impedance cardiograph, the NCCOM-3 (BoMed Medical Manufacturing Ltd), which also measures heart rate and then calculates cardiac output and index. It is non-invasive, requiring only the application of 10 electrodes to the neck and chest, and provides a continuous estimate of cardiac index. The device has many potential applications, for example a continuous measure of cardiac output combined with a pulse oximeter and a mixed venous oximetry pulmonary artery catheter would allow continuous monitoring of oxygen delivery and consumption. However, during initial assessment of this device in our Intensive Care Unit, it became apparent that in patients with severe sepsis the cardiac indexes determined by thermodilution and by bioimpedance often differed. We report a comparative study of the NCCOM-3 and thermodilution for measurement of cardiac index in patients with severe sepsis.

PATIENTS AND METHODS

The study was approved by the institutional Ethics Committee. Patients were selected for study if they already had a pulmonary artery catheter placed for haemodynamic assessment and clinical signs consistent with systemic sepsis [6], with either microbiological evidence of a source of sepsis or positive blood cultures. All patients were undergoing mechanical ventilation of the lungs using intermittent mandatory ventilation or controlled ventilation. No alterations in therapy were made for the purpose of the study.

We studied 19 patients, usually twice daily whilst they were clinically septic. Five patients had a perforated viscus, two had pancreatitis, four had pulmonary infection, four had sepsis following trauma, two had infection following aortic aneurysm surgery, one patient had toxic shock syndrome and one had an infected hip arthroplasty. A total of 242 pairs of measurements were made.

Cardiac index was determined from thoracic bioimpedance changes using the NCCOM-3 device (revision 6 software [7]). Eight current injection and voltage sensing electrodes were placed on the neck and thorax and two additional electrodes were placed on the right sternal border and over the apex beat to provide a high-quality ECG signal. All the electrodes were placed according to the manufacturer's instructions, and electrodes were left in place between measurements unless they interfered with the patient's care. Neck dressings for internal jugular catheters were removed to allow electrode positioning where required. The ECG and bioimpedance ($\delta Z/\delta t$) signals were taken from the analog output port on the NCCOM-3 to a twin-channel chart recorder (Lectromed Ltd) to allow a visual check on the signal quality. The NCCOM-3 digital output

J. D. YOUNG*, F.R.C.ANAES.; P. McQUILLAN, F.R.C.ANAES.; Intensive Care Unit, Nuffield Department of Anaesthetics, John Radcliffe Hospital, Headley Way, Oxford. Accepted for Publication: July 17, 1992.

*Present address, for correspondence: Nuffield Department of Anaesthetics, Radcliffe Infirmary, Woodstock Road, Oxford OX2 6HE.

port was connected to a "Thinkjet" printer (Hewlett–Packard Ltd) to provide a permanent printed record. The patient's sex, height and weight were introduced into the NCCOM-3 keyboard, and the calculated body surface area recorded. Cardiac index was taken as the average during 60 heartbeats accepted by the NCCOM-3 recorded at the same time as the thermodilution measurements.

Thermodilution determinations of cardiac output were performed using a COM-1 cardiac output computer (Edwards Laboratories) with a closed injectate delivery system and in-line temperature sensor ("CO-set" system, Edwards Laboratories). Injectate temperatures were always less than 10 °C, and injections were made manually during expiration. Measurements were always made by one of the authors; the average of three measurements was used. Cardiac output was converted to cardiac index using the body surface area calculated by the NCCOM-3 thoracic bioimpedance computer.

The results were analysed using linear regression analysis and by the method described by Bland and Altman [8] for comparing two methods of measurement, which allows bias and precision to be assessed numerically and graphically.

The NCCOM-3 calculates cardiac output by using the formula:

$$\dot{Q} = \mathrm{HR} \times V_{\mathrm{EPT}} \times \mathrm{VET} \times \delta Z/\delta t\mathrm{max}/Z^0$$

where $\dot{Q}$ = cardiac output (litre min^{-1}); HR = heart rate (beat min^{-1}); VET = ventricular ejection time (s); Z^0 = baseline thoracic impedance (Ω); $\delta Z/\delta t\mathrm{max}$ = maximum rate of change of thoracic impedance during systole (Ω s^{-1}). V_{EPT} is the volume of electrically participating tissue, calculated as:

$$V_{\mathrm{EPT}} = d \times (0.17 \times H)^3/4.25$$

where H = height (cm); d = ratio of actual to ideal weight multiplied by the ratio of the calculated thoracic blood volume to the calculated ideal thoracic blood volume [5].

The cardiac output is scaled with the body surface area calculated from height and weight (body surface area = [height in cm]$^{0.725}$ × [weight in kg]$^{0.425}$ × 0.00718) to obtain cardiac index. To determine if one factor caused the difference or ratio between cardiac index measured by the two techniques, both the difference and ratio of the two stroke volume measurements were regressed against the values for heart rate, height, weight, Z^0 and ventricular ejection time (determined by the NCCOM-3) using multiple linear regression. The ventricular ejection time was also computed from the heart rate using the formula described by Weissler and Garrard [9] and compared with the ratio and difference of the two stroke volume measurements using linear regression. The stroke volume was used for the regressions to minimize mathematical linkage of the values being regressed.

RESULTS

The scatter plot of cardiac index measured by bioimpedance against cardiac index measured by thermodilution is shown in figure 1. The regression line is $y = 0.16x + 2.56$; the correlation coefficient 0.36. There is a large scatter in the results.

If the data are presented as the difference between simultaneous cardiac index estimates plotted against the mean of the values, a plot as shown in figure 2 results [8]. This accentuates what the regression line revealed: there is generally an increasing error with increasing cardiac index. The bias is 1.69 litre min^{-1} m^{-2} with limits of agreement of ±2.48 (+4.17 to −0.79) litre min^{-1} m^{-2}. The limits of agreement represent the 95% confidence limits for the estimate of a value of cardiac index that would be recorded by bioimpedance for a given value of cardiac index determined by thermodilution in the range 2–8 litre min^{-1} m^{-2}.

The linear regression line for cardiac index measured by the NCCOM-3 on cardiac index measured by thermodilution has a large offset (2.56 litre min^{-1} m^{-2}) and a low gradient (an increase of 0.16 litre min^{-1} m^{-2} in the NCCOM-3 reading for every litre min^{-1} m^{-2} increase in the thermodilution value). If this is regarded as a "calibration" error in the NCCOM-3, this can be corrected mathe-

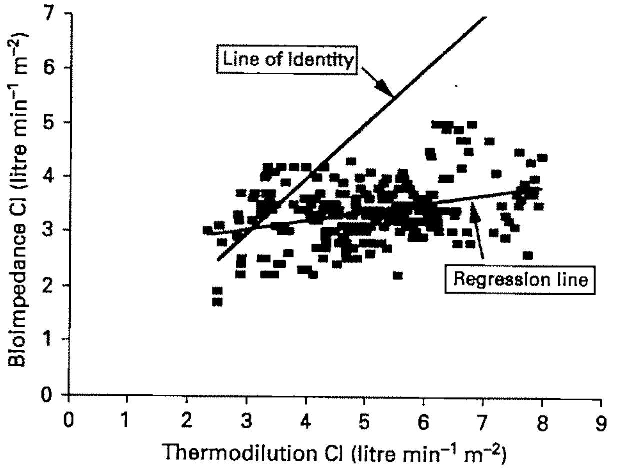

FIG. 1. Cardiac index measured by bioimpedance plotted against cardiac index measured simultaneously by thermodilution.

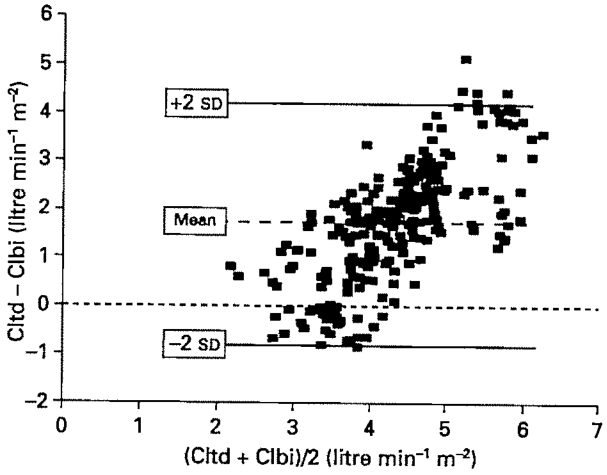

FIG. 2. Difference between simultaneous measurements of cardiac index measured by thermodilution (CItd) and by bioimpedance (Cbi) plotted against the mean of the two values. The mean difference (the bias) and the limits of agreement (±2 SD of the difference values) are also shown.

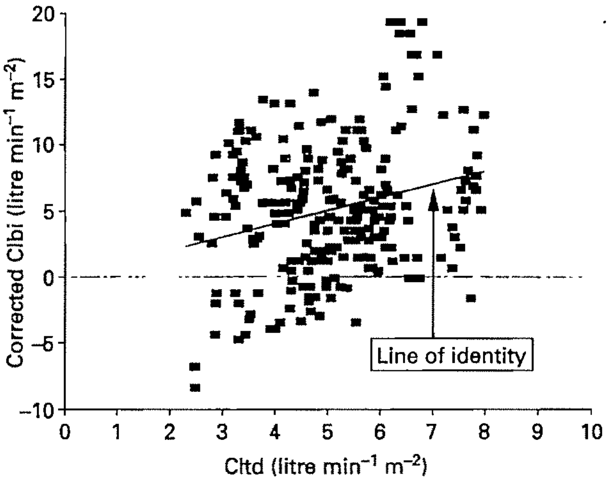

FIG. 3. Cardiac index measured by thermodilution (CItd) plotted against the "corrected" cardiac index measured simultaneously by bioimpedance (CIbi). The bioimpedance cardiac index was corrected using the regression of the thermodilution values on the bioimpedance values, so the line of identity and the regression line coincide.

matically—the regression of thermodilution on NCCOM-3 cardiac index values. The resulting plot is shown in figure 3. Although the regression line now has a gradient of 1 and an offset of 0, the correction has not improved the scatter of the results around the regression line. Thus, although the bias has now been eliminated, there is virtually no change in the limits of agreement determined by the Bland and Altman technique (±2.46 litre min^{-1} m^{-2}).

The mean value for baseline thoracic impedance (Z^0) was 12.4 (SD 3.2) Ω (range 6.2–20.2 Ω). Neither the difference between the values for stroke volume measured by thermodilution and bioimpedance, nor the ratio of the two values showed any dependence on heart rate, Z^0 or ventricular ejection time, either measured by the NCCOM-3 or calculated from the heart rate. Both the difference and ratio of the two values for stroke volume were dependent on height and weight ($P < 0.0001$). However, the value for stroke volume measured by thermodilution also correlated strongly with height and weight (both $P < 0.0001$), so this probably represents an increasing difference and ratio of the two values for stroke volume with increasing stroke volume, and not an error dependent on height or weight.

DISCUSSION

There have been many human studies comparing measurement of stroke volume or cardiac output using bioimpedance with other established methods in volunteers or patients. Bioimpedance measurements of stroke volume correlate with measurements made by left ventriculograms [10], by echocardiography [11, 12], by the direct or indirect Fick method [13–18] and by dye dilution [4, 14, 19–22], although there is a large range of correlation coefficients (0.29–0.99) and the regression lines are often displaced from the line of identity.

The widespread use of pulmonary artery catheters in critical care units has facilitated comparison of cardiac output measured by thermodilution and bioimpedance in seriously ill patients [23–30]. These comparisons showed regression lines with gradients less than 1 (0.28–0.98) and positive intercepts (0.35–2.61 litre min^{-1}). Thus the bioimpedance technique would be expected to indicate a cardiac output that exceeds the output measured by thermodilution at low cardiac outputs, but would underestimate at higher cardiac outputs. The correlation coefficients for these studies ranged from 0.41–0.91. All these studies with the exception of that by Donovan and colleagues [29] used the NCCOM-3 impedance cardiograph.

The use of correlation coefficients to compare two methods of measurement has been criticized as they do not give any indication of the error that can be expected when one method of measurement is substituted for another. To overcome this, the method of Bland and Altman [8] may be used to estimate the bias and precision of one method compared with another. Gotshall, Wood and Miles [24] and Wong and colleagues [26] used the technique to compare cardiac output measured by thermodilution and bioimpedance in critically ill patients. They showed bias values of −0.67 and −0.03 litre min^{-1} and "limits of agreement" of +2.77 to −4.11 litre min^{-1} and +3.24 to −3.30 litre min^{-1}, respectively. As a result, both groups urged caution in the use of bioimpedance as a monitor of absolute values of cardiac output.

The comparison of thermodilution and bioimpedance measurements of cardiac output in patients with sepsis has not been examined directly. Bernstein [27] observed that in vasodilated septic patients the bioimpedance method underestimated cardiac output, and suggested this was caused by shunting of the current via vasodilated skin and muscle, thus bypassing the lungs and great vessels. Wong and colleagues [26] analysed a subgroup of septic patients and found a correlation coefficient of 0.73 and a regression line close to the line of identity, and concluded that sepsis was not a factor likely to influence the correlation between thermodilution and bioimpedance measurements of cardiac output.

In this study we found a very poor correlation between the cardiac index measured by bioimpedance and thermodilution. The bioimpedance method overestimated at low cardiac index and markedly underestimated at high cardiac index, with a large scatter in the results. The correlation coefficient is the smallest reported for any comparison of bioimpedance and thermodilution methods on any group of critically ill patients. The limits of agreement using Bland and Altman's technique are very wide, implying the techniques are not interchangeable. Even if the bioimpedance results are mathematically corrected to cause the regression line to match the line of identity, the scatter of the results is such that it is impossible to replace thermodilution methods with bioimpedance.

We used accepted methods for measurement of cardiac index by thermodilution and tried to ensure that cardiac index determinations using bioimpedance and thermodilution were made over as many of the same cardiac cycles as possible. No patient had tricuspid incompetence as judged by the central venous pressure trace. Cold injectate was used, to minimize errors. The thermodilution technique was identical to that used in other comparative studies of thermodilution and bioimpedance that have shown far better correlation. In a study performed just before this study in the same Intensive Care Unit using the same equipment and techniques on non-septic, artificially ventilated patients, Jewkes and colleagues [31] showed a correlation coefficient of 0.72 and limits of agreement of -2.6 to $+0.89$ litre min^{-1} for cardiac output. Thus we attribute the large discrepancy in the two methods in this study partially to errors in the bioimpedance technique specific to septic patients. However, the accuracy of thermodilution measurements of cardiac output in patients with sepsis has not been investigated by comparison with other techniques except suprasternal Doppler flow measurement [26], so there is a small chance that errors in thermodilution measurements caused the discrepancy.

The mean thoracic bioimpedance (Z^0) of the patients in this study was small (12.4 Ω); a normal value for supine patients is 22.5–24 Ω, that in the presence of pulmonary oedema, 18 Ω [32]. The small value we attribute to non-cardiogenic pulmonary oedema (adult respiratory distress syndrome) and pulmonary atelectasis, which alter the air–fluid relationships in the lungs and hence the lung resistivity. A reduction in thoracic bioimpedance has been noted with pleural effusion, and an increase with pneumothorax, dehydration and chronic obstructive lung disease [33], which would support this hypothesis, and in general the patients with more severe lung infiltrates on chest radiographs had smaller Z^0 values. Alternatively, as Bernstein [5] has suggested, the reduced Z^0 in sepsis may be caused by muscle and cutaneous vasodilatation. The value of thoracic bioimpedance was not directly related to the difference or the ratio between the values for stroke volume from the two methods of measurement, as assessed by multiple linear regression. However, the maximum change in bioimpedance is scaled with the Z^0 value in the calculation of cardiac index by bioimpedance, and the small values of Z^0 in these patients may be outside the range over which the assumptions used in the bioimpedance technique are valid, and cause a non-linear error.

It has been suggested that, although the values for cardiac index do not agree with the values obtained with thermodilution, in any one patient the bioimpedance can monitor trends in cardiac output [31]. The rationale for this is that each individual patient has a different relationship between cardiac index measured by thermodilution and bioimpedance, with a different gradient and offset to the regression line, and reasonably low limits of agreement. When results are pooled, as in this study, the resulting pooled limits of agreement are much worse than the individual values. For individual patients, the limits of agreement were between ± 0.29 and ± 2.55 litre $\text{min}^{-1}\,\text{m}^{-2}$ around the bias values, the average limits of agreement were ± 1.2 litre $\text{min}^{-1}\,\text{m}^{-2}$. Thus on average, even in an individual patient, to be 95 % certain that one value of cardiac output is significantly different from another measured by bioimpedance, the difference between the two readings has to be greater than 1.2 litre $\text{min}^{-1}\,\text{m}^{-2}$. Thus, even as a monitor of changes in cardiac index in individual septic patients, the bioimpedance technique is too insensitive for clinical use. It might be of value if the patients with low limits of agreement could be identified, but this is not possible.

A significant proportion of the thoracic bioimpedance change during systole may arise because of changes in the blood volume of the lungs [1, 34]. If the change in thoracic bioimpedance that occurs in systole is caused by an increase in pulmonary blood volume by a volume equivalent to the right ventricular stroke volume, then the stroke volume might be expected to be related to the change in bioimpedance during systole, δZ, and not its maximum first derivative $\delta Z/\delta t\text{max}$. This, however, does not occur; blood also leaves the lungs during systole and so the maximum rate of change of bioimpedance, $\delta Z/\delta t\text{max}$, is used. This represents the maximum rate of increase in blood volume (i.e. flow) in the lungs and occurs in early systole when the majority of the incoming pulmonary blood flow would be expected to expand capacitance vessels and remain within the lung. By extrapolating this flow over the whole of systole, a value for stroke volume is obtained. In septic patients requiring artificial ventilation, pulmonary hypertension is an almost universal finding, and pulmonary haemodynamics are markedly altered. Thus the relationship between $\delta Z/\delta t\text{max}$ and overall stroke volume may not remain the same, and so the extrapolations used in the thoracic bioimpedance method to calculate the cardiac index may fail.

There is also a more fundamental reason why the bioimpedance method does not measure cardiac index in the septic patient. The method relies on the oversimplified assumption that the thorax is a homogeneous conductor, shaped like a truncated cone. The change in impedance between the top and bottom of the thorax is attributed to changes in the blood content of the thorax. The impedance *decreases* during systole, implying that the thoracic blood volume *increases* during systole. This is physiologically unlikely; the change in impedance is probably caused by redistribution of blood within the thorax, which is thus not acting as a homogeneous conductor, and so the central theory of the method is suspect. Therefore, although the method works with normal subjects, if the underlying theory is unsound there is no reason why it should work in all circumstances.

ACKNOWLEDGEMENTS

DIFFERENTIAL EFFECTS OF ALFENTANIL, FENTANYL, PETHIDINE AND LIGNOCAINE ADMINISTERED INTRATHECALLY ON NOCICEPTIVE RESPONSES EVOKED BY LOW AND HIGH FREQUENCY STIMULATION OF SOMATIC NERVES

C. WANG, A. KOUTSOUKOU-DRITSOPOULOU, M. K. CHAKRABARTI, A. HOLDCROFT AND J. G. WHITWAM

SUMMARY

We have studied in anaesthetized dogs the effects of alfentanil, fentanyl, pethidine and lignocaine administered intrathecally on nociceptive responses evoked by low and high frequency supramaximal electrical stimulation of the tibial and radial nerves. Doses were selected to abolish both Aδ and C fibre somatosympathetic reflexes to single stimuli. Pethidine and lignocaine eliminated reflex pressor and heart rate responses to repeated single stimuli and almost completely abolished responses to train stimulation. The pressor response to single stimuli was abolished by fentanyl and reduced by alfentanil, but these drugs did not reduce significantly this response to train stimulation, suggesting a stimulation rate-dependent effect. Of the opioids, only pethidine had an effect comparable to that of lignocaine. The absence of sympathetic block and antagonism by naloxone imply a lack of significant local anaesthetic effect. We suggest that the greater analgesic efficacy of pethidine is a result of endogenous synergism between a minor local anaesthetic and a major opioid effect. (Br. J. Anaesth. 1993; **70**: 63–69)

KEY WORDS

Analgesics: alfentanil, fentanyl, pethidine. Anaesthetics, local: lignocaine. Anaesthetic techniques: spinal. Nerves: somatic, stimulation frequency. Reflexes: somatosympathetic.

Opioids and local anaesthetic drugs cause analgesia when applied to the spinal cord; however, the efficacy of opioids for the relief of acute pain in some circumstance (for example during surgical or obstetric procedures) is often inadequate compared with local anaesthetics [1, 2]. The addition of small concentrations of local anaesthetics to opioids may be used to improve the quality of pain relief [2, 3]. Differences in the efficacy of the analgesic response to opioids may relate to the type of stimulation which presents to the dorsal horn cells. It is known that acute pain is accompanied usually by sympathetic responses which have been used to measure pain by recording either sympathetic nerve activity or, for example, changes in arterial pressure. In contrast, pain without acute episodes may not be accompanied by overt sympathetic responses. The differences in the type of stimulation are either its origins or its severity, which would include intensity and the numbers and firing frequency of afferent fibres.

This study was undertaken to test if the frequency of stimulation can modulate the antinociceptive effects of alfentanil, fentanyl, pethidine and lignocaine. We chose two different types of afferent somatic stimuli. The first was a series of single electrical stimuli supramaximal for activation of both Aδ and C fibre-mediated responses at 0.33 Hz, and the second comprised stimuli of the same intensity applied as 10-s trains at 30 Hz.

MATERIALS AND METHODS

Investigations were carried out in 15 greyhound dogs weighing between 27.6 and 32.6 kg (approved under Home Office Licence No PPL 70/01654). Anaesthesia was induced with methohexitone 15 mg kg^{-1} i.v., the trachea was intubated and the lungs ventilated with oxygen enriched air. Anaesthesia was maintained using 1% α-chloralose in an initial bolus dose of 30 mg kg^{-1} i.v. followed by a continuous infusion of 17.5 mg kg^{-1} h^{-1} i.v. and muscle paralysis was maintained using suxamethonium 10 mg i.v. every 30 min. The left femoral artery and vein were cannulated for arterial pressure recording, blood sampling, drug administration and fluid infusion. Arterial pH was maintained in the range 7.30–7.35, Pa_{O_2} 20–27 kPa, Pa_{CO_2} 4.5–5.5 kPa and oesophageal temperature 37–39 °C.

A site for intrathecal (i.t.) drug injection was prepared by removal of the lamina of the 2nd and 3rd lumbar vertebrae, exposure of the dura mater and intradural cannulation with a 22-gauge Y-can. Lateral superficial branches of the radial and tibial

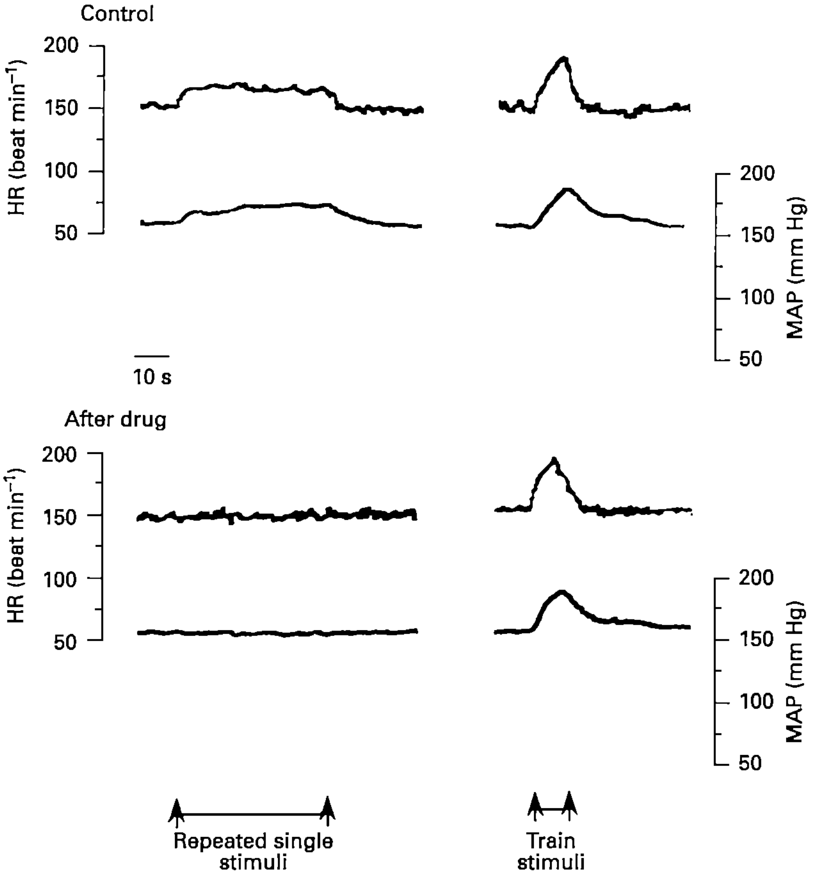

FIG. 1. Typical recording of reflex responses in the heart rate (HR) and mean arterial pressure (MAP) evoked by repeated single stimuli (0.33 Hz, 30 V, 0.5 ms) and a 10-s train of stimuli (30 Hz, 30 V, 0.5 ms) applied to the tibial nerve before (Control) and after fentanyl 0.15 mg i.t.

nerves were exposed in the left foreleg and right hind leg, respectively. Both nerves were desheathed, cut distally, immersed in mineral oil and mounted on silver electrodes. The renal sympathetic nerves were exposed retroperitoneally along the right renal artery. Single fascicles of nerve were desheathed, cut distally near the kidney, immersed in a mineral oil pool and mounted on silver–silver chloride electrodes. The preparation was maintained throughout in a lateral position with head up tilt of 15° to prevent ascending spread of intrathecal drugs.

The mean arterial pressure (MAP) was measured with a calibrated strain gauge and displayed together with the beat-by-beat heart rate (HR) using a heated stylus recording system (Devices M19).

Repeated single supramaximal electrical stimuli (frequency 0.33 Hz, intensity 30 V and duration 0.5 ms) and 10-s trains of high frequency stimuli (30 Hz, intensity 30 V and duration 0.5 ms) were applied to both the tibial and radial nerves using a Grass S88 stimulator with matched directly coupled isolation unit (Grass 478A). Efferent activity in renal sympathetic nerves was processed through a preamplifier (Tektronix type 122) and displayed on a dual-beam oscilloscope (Tektronix type 565). Average transients of the evoked sympathetic responses were obtained using a Neurolog system (NL750 Digitimer) and 16 responses were averaged on each occasion. The averaged responses were rectified and integrated (Neurolog NL90) and both signals were displayed on a pen recorder (Devices MX2).

After being set up, the preparation was allowed to stabilize for 30 min, when control data were obtained. To record the evoked responses in MAP and HR caused by repeated single stimuli, the stimulation was sustained for up to 1 min to allow development and stabilization of the maximal response in MAP and HR. The changes in MAP and HR evoked by repeated single and train stimuli were measured as the peak responses (fig. 1). The MAP and HR were then allowed to return to prestimulus control values. The evoked response in renal sympathetic nerves could not be recorded during train stimulation, as the repeated stimulus artefact interferes with and distorts the sympathetic signal.

The doses of alfentanil, fentanyl, pethidine and lignocaine were chosen to just abolish the evoked reflexes in renal sympathetic nerves to repeated single stimuli applied to the *tibial nerve* in a series of preparations. The doses for alfentanil 7.5 mg (5 mg ml^{-1}) and fentanyl 0.15 mg (0.05 mg ml^{-1}) had been determined in previous studies [4, 5]. In the

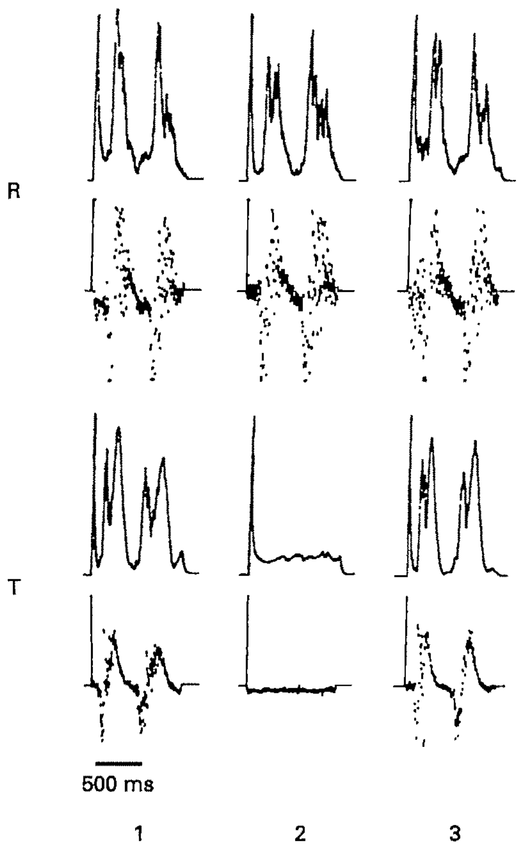

FIG. 2. Typical recording of the effects of pethidine administered i.t. followed by naloxone i.v. on the responses in a renal sympathetic nerve evoked by a single electrical stimulus (30 V, 0.5 ms duration, 0.33 Hz) applied to the tibial (T) and radial (R) nerves. Lower trace: average transient of 16 responses. Upper trace: rectified integral of averaged signal. 1 = Control; 2 = 5 min after pethidine 30 mg i.t.; 3 = 5 min after naloxone 2 mg i.v. It can be seen that pethidine did not affect the radial somato-sympathetic reflexes (upper traces) to any significant degree and that its effect on tibial nerve stimulation was antagonized completely by naloxone. This indicates that the action of pethidine is not primarily a local anaesthetic effect.

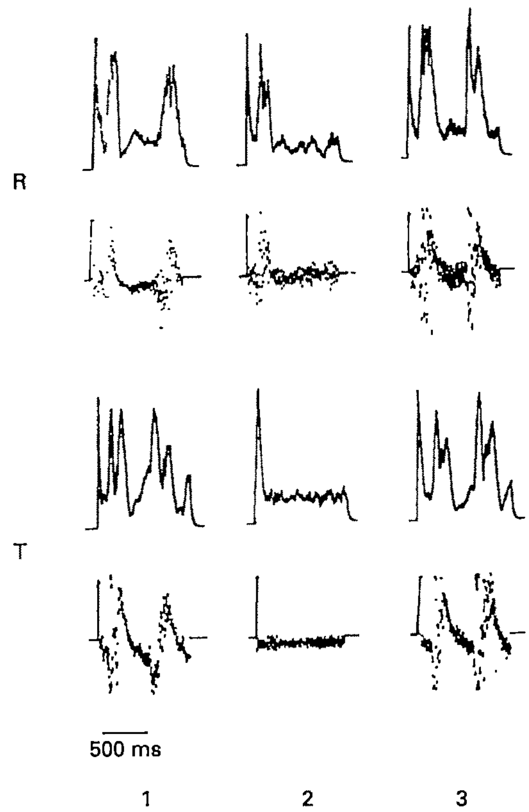

FIG. 3. Effects of alfentanil administered i.t. followed by naloxone i.v. on the responses in a renal sympathetic nerve evoked by a single electrical stimulus (30 V, 0.5 ms duration, 0.33 Hz) applied to the tibial (T) and radial (R) nerves. Lower trace: average transient of 16 responses. Upper trace: rectified integral of averaged signal. 1 = Control; 2 = 5 min after alfentanil 7.5 mg i.t.; 3 = 5 min after naloxone 2 mg i.v.

present study, preliminary observations showed that the doses of pethidine and lignocaine which just abolished the somatosympathetic reflexes were 30 mg (20 mg ml^{-1}) and 10 mg (10 mg ml^{-1}) i.t., respectively. Alfentanil, fentanyl and pethidine were administered in each of five preparations. Five minutes after each drug administration, averaged evoked responses in the renal sympathetic nerve to repeated single stimulation applied to the tibial nerve confirmed that the drug had abolished the sympathetic response. The reflexes evoked in renal sympathetic nerves by repeated single stimulation of the *radial nerve* were recorded to provide a control and to determine if there was a direct effect on the efferent sympathetic pathway. When a stable state was established, then either repeated single (0.33 Hz) or 10-s trains (30 Hz) of stimuli were applied in a random sequence. The study was then repeated with the repeated single and train stimuli in reversed order. Reflex responses in MAP and HR were recorded. When the study was completed, naloxone 2 mg i.v. was administered. When the evoked reflexes in renal sympathetic nerves, MAP and HR returned to values similar to control, the sequence described above was repeated to confirm that the preparation had returned to its control state. Lignocaine 10 mg (10 mg ml^{-1}) was then injected i.t. in all preparations and a similar random series of stimulations and measurements was repeated. The duration of these experiments varied between 7 and 9 h.

Statistical analysis was performed with analysis of variance, where appropriate, followed by paired Student's *t* tests.

RESULTS

Somatosympathetic reflexes

Tibial nerve stimulation. Alfentanil 7.5 mg, fentanyl 0.15 mg, pethidine 30 mg and lignocaine 10 mg administered i.t. abolished both the Aδ and C reflexes in the renal sympathetic nerves evoked by single stimuli applied to the tibial nerves of all the dogs (figs 2–4).

Radial nerve stimulation. The somatosympathetic reflexes evoked by radial nerve stimulation were unaffected by fentanyl and pethidine (fig. 2). In contrast, in preparations receiving alfentanil, whereas the Aδ fibre-mediated reflexes in renal sympathetic nerves did not change significantly, the C fibre-mediated longer latency reflex was abolished, suggesting either systemic absorption or supraspinal spread (fig. 3) [4]. Lignocaine i.t. completely abolished the reflexes in renal sympathetic nerves to both tibial and radial nerve stimulation (fig. 4), because it blocks the efferent sympathetic nerves.

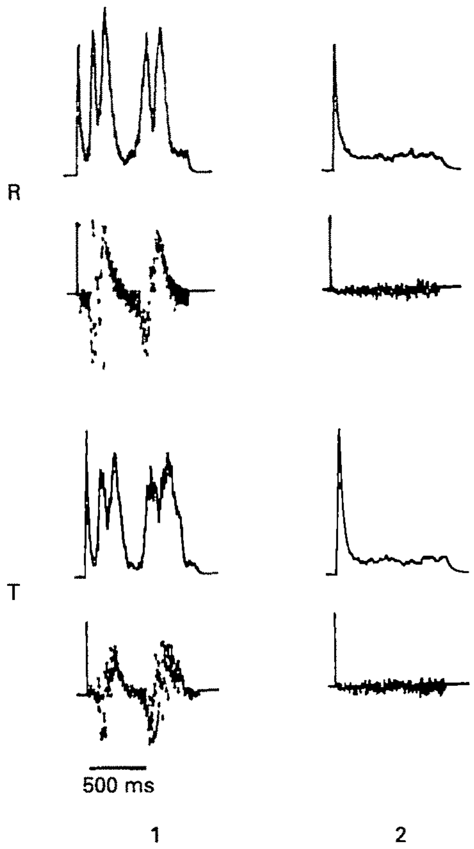

FIG. 4. Effects of lignocaine administered i.t. on the evoked responses in a renal sympathetic nerve by a single electrical stimulus (30 V, 0.5 ms duration, 0.33 Hz) applied to the tibial (T) and radial (R) nerves. Lower trace: average transient of 16 responses. Upper trace: rectified integral of averaged signal. 1 = Control; 2 = 5 min after lignocaine 10 mg i.t.

Arterial pressure and heart rate

Tibial nerve stimulation. It may be seen that the increase in MAP caused by repeated single stimulation of the tibial nerve was eliminated by fentanyl, pethidine and lignocaine, and markedly reduced by alfentanil (table I; figs 1, 5). The increase in MAP induced by trains of high frequency stimulation of the tibial nerve was abolished completely by lignocaine and only a very small residual pressor response remained in preparations receiving pethidine (fig. 5). In contrast, after fentanyl and alfentanil, the evoked increase in MAP caused by high frequency train stimulation was slightly greater than control (ns). The reflex increase in HR during single stimulation of the tibial nerve was abolished completely by fentanyl, lignocaine and pethidine (table I; figs 1, 6); after alfentanil an increase in HR of 6.4% was not significantly different from the control value of 7.7%. The responses to trains of stimuli were more variable. For example, there was a significant increase in the heart rate response after alfentanil from 15% to 54.3%. In contrast, after fentanyl the increase in HR caused by trains of stimuli remained almost unchanged compared with the control responses, and this response was abolished by both pethidine and lignocaine.

Radial nerve stimulation. The reflex increases in MAP and HR caused by either repeated single or train stimulation of the radial nerve were similar to control values after alfentanil and fentanyl. While this was also true for MAP with pethidine (table I), the response in HR to low frequency stimulation was reduced. However, in the group receiving pethidine there was an increase in resting mean heart rate of 9 beat min^{-1} after i.t. administration (table I) (ns). This could explain this phenomenon, as, during train stimulation, a larger sympathetic response occurred which increased the HR to a mean value of 201 beat min^{-1},—a mean increase of 39 beat min^{-1} in the pethidine group compared with an increase in HR in the fentanyl group of 34 beat min^{-1} (table I). Lignocaine i.t. caused a small but statistically non-significant reduction in the reflex increases in MAP and HR in response to both low and high frequency stimulation (table I).

DISCUSSION

High strength electrical stimulation of somatic nerves causes reflex responses in the autonomic nervous system which are manifest, for example, by changes in arterial pressure [6, 7]. Directly recorded sympathetic nerve responses to single electrical stimuli applied to a somatic nerve show two bursts of activity mediated by afferent Aδ and C fibres [8, 9]. In this study the doses of alfentanil, fentanyl, pethidine and lignocaine used were the minimal required to just eliminate both the Aδ and C fibre-mediated responses evoked in renal sympathetic nerves to repeated single supramaximal electrical stimuli applied to the tibial nerve. The increase in MAP in response to repeated single stimulation was also abolished completely by fentanyl, pethidine and lignocaine. A large dose of alfentanil was required to abolish the Aδ reflex, with evidence of baroreflex sensitization causing a significant reduction in both MAP and HR ($P < 0.05$) (table I, fig. 3) and a small arterial pressure response persisted (fig. 5). This confirms previous observations which also indicated that the elimination of the tibial Aδ fibre-mediated reflex after alfentanil required a dose which had more general central effects, resulting either from systemic absorption or from supraspinal spread [4].

During high frequency train stimulation with the same stimulus intensity, the reflex increase in MAP was abolished almost completely by pethidine and abolished completely by lignocaine. In contrast, the evoked increases in MAP did not change significantly from control values after both alfentanil and fentanyl; this suggests that the antinociceptive effect of these opioids is dependent on the frequency of stimulation. Thus a dose which abolishes the effect of low frequency afferent stimulation does not necessarily provide adequate "analgesia" at higher frequencies of stimulation even when its duration is relatively short—10 s in the present study. This phenomenon could be one factor explaining the relative ineffectiveness of the opioids, compared with local anaesthetic drugs, in relieving severe intra-operative pain.

A further increase in the intrathecal dose of fentanyl could possibly cause depression of the nociceptive response in arterial pressure evoked by high frequency stimulation. However, this may not

TABLE I. *Mean (SD) mean arterial pressure (MAP) and heart rate (HR) from non-stimulation control values (resting), repeated single stimulation (0.33 Hz, 30 V, duration 0.5 ms) and 10-s train of stimulation (30 Hz, 30 V, duration 0.5 ms) applied to the tibial and radial nerves before and after drug treatment.* $P < 0.05$: ** compared with non-stimulation either during control or after drug administration; † compared with non-stimulated control values before and after drug administration, indicating a degree of baroreceptor sensitization in the alfentanil group*

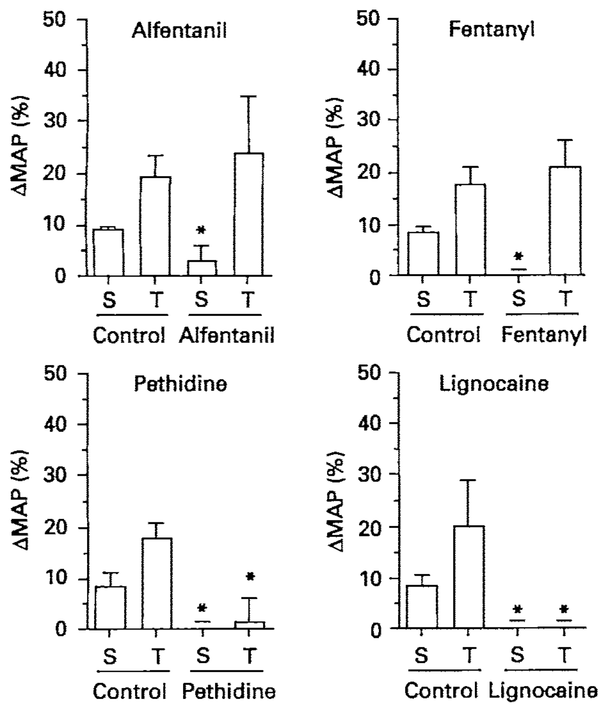

FIG. 5. Percentage increase (mean, SD) in mean arterial pressure (MAP) from non-stimulation control evoked by repeated single stimulation (S) and 10-s train stimulation (T) applied to the tibial nerve before and after alfentanil 7.5 mg ($n = 5$), fentanyl 0.15 mg ($n = 5$), pethidine 30 mg ($n = 5$) and lignocaine 10 mg ($n = 15$), administered i.t. $*P < 0.05$ compared with control.

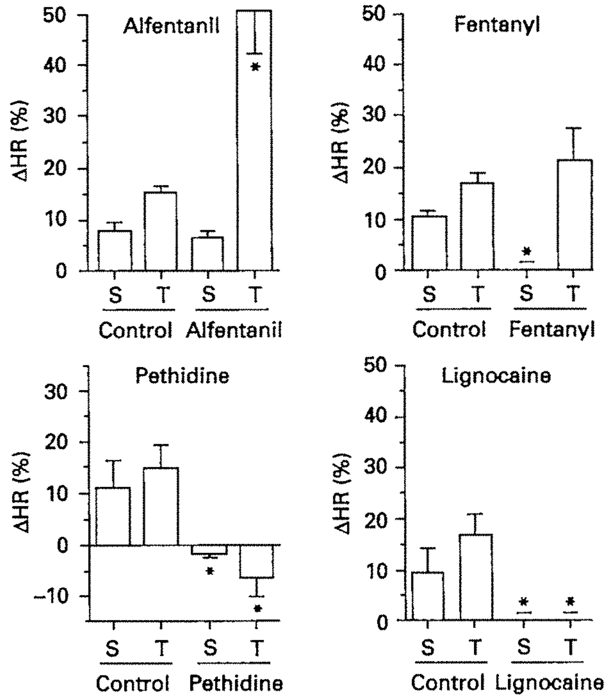

FIG. 6. Percentage increase (mean, SD) in heart rate (HR) from non-stimulation control evoked by a repeated single stimulation (S) and 10-s train tetanic stimulation (T) applied to the tibial nerve before and after alfentanil 7.5 mg ($n = 5$), fentanyl 0.15 mg ($n = 5$), pethidine 30 mg ($n = 5$) and lignocaine 10 mg ($n = 15$), administered i.t. $*P < 0.05$ compared with control.

occur with alfentanil, because the dose used in these experiments was very large—7.5 mg i.t., with evidence of cardiovascular effects related to either systemic absorption or supraspinal diffusion. In addition, the depression and abolition of the reflex nociceptive cardiovascular response to train stimuli may not be achieved even when the dose of fentanyl is increased to a very high concentration. It is reported that the effectiveness of spinal opioids in providing further analgesia in man does not always occur with an increase in dose beyond an adequate level of analgesia [2]. The dose of fentanyl administered in this study was greater than that used usually in clinical practice [2]. Moreover, the potential risk of respiratory depression is also increased when larger doses of opioids are used.

The site of action of spinally applied opioids is in the dorsal horn [10, 11] and fentanyl, alfentanil and pethidine act via mu opioid receptors which involve potassium channels [12], whereas local anaesthetic drugs act predominantly on the sodium channels in axonal membranes [13]. There is evidence that the effect of local anaesthetics may differ on sympathetic, sensory and motor fibres [14]. Cousins [13] suggested that block of primary afferent transmission is a more potent method of producing pain relief than local inhibition in the spinal cord—a view based on evidence from clinical pain studies with spinally applied opioids and local anaesthetics.

Pethidine was introduced in 1939 [15]. In 1946, Way [16] showed that it could produce corneal analgesia, sciatic nerve block and intradermal analgesia, suggesting that it was a local anaesthetic. Until the present study, this was the basis of the explanation for its superiority over other opioids as an analgesic drug when applied topically [2, 17]. However, in this study pethidine had an effect similar to that of lignocaine on the reflex increase in MAP in response to both repeated single and train stimulation applied to the tibial nerve. This could be interpreted as a local anaesthetic effect but there was no evidence for this, as its effects were antagonized completely by naloxone (fig. 2). Also, comparison of the effects of pethidine and lignocaine on the somatosympathetic responses evoked by radial nerve stimulation showed that, while pethidine (fig. 2) blocked the afferent pathway, there was no evidence of efferent sympathetic block. This contrasts with lignocaine, which blocked both the efferent sympathetic and afferent nociceptive pathways (fig. 4). The increase in MAP evoked by both single and train stimulation of the radial nerve was reduced slightly after lignocaine, compared with pethidine, which would be compatible with limited local block of the efferent sympathetic system.

Pain relief in labour following extradural opioids has been disappointing and the addition of bupivacaine is recommended [18–20]. However, i.t. pethidine has been used successfully in labour [21] and for Caesarean section [22, 23]. It has provided satisfactory saddle block for perineal surgery [24], and it has been used for prostatic surgery [25]. It has also been reported that, after major abdominal surgery, a combination of extradural morphine and local anaesthetic provided better analgesia than morphine alone [3] and there is synergism between morphine and lignocaine [26]. Synergism between this putative local anaesthetic property and the major opioid action, observed in the present study, could explain its greater effectiveness compared with fentanyl and alfentanil. For example, a combination of 0.0625 % bupivacaine and 0.0002 % fentanyl has been shown to produce analgesia in labour [27].

Another possible explanation for the effectiveness of pethidine is that it could, conceivably, act at kappa receptors, in addition to mu receptors, in the spinal cord. Kappa receptors account for more than 50 % of opioid receptors in the human spinal cord [28]. The kappa receptor may also predominate in some other higher mammalian species [29].

In conclusion, this study shows that an intrathecal dose of opioids which causes a reduction in the reflex sympathetic and cardiovascular responses to repeated single nociceptive stimuli may not depress such reflexes to stimulation of the same intensity but at a greater frequency. It provides a hypothesis for one contributory factor to the observation of the relative ineffectiveness of opioid analgesia in many clinical situations. It also shows that pethidine is a more effective "analgesic" drug than either fentanyl or alfentanil. It does not cause measurable block of efferent sympathetic activity, which could be an advantage compared with lignocaine. The fact that its effects are antagonized by naloxone allow a further intriguing hypothesis that a single drug, pethidine, may provide endogenous synergism between a small local anaesthetic effect and a major opioid action, which would explain or reconcile many previous experimental and clinical observations.

GENETIC LINKAGE ANALYSIS OF CHROMOSOME 19 MARKERS IN MALIGNANT HYPERTHERMIA

S. P. BALL, H. R. DORKINS, F. R. ELLIS, J. L. HALL, P. J. HALSALL, P. M. HOPKINS, R. F. MUELLER AND A. D. STEWART

SUMMARY

Previous studies have reported that malignant hyperthermia susceptibility is caused in some families by inherited variation in a gene located on the short arm of chromosome 19 near to, or identical with, the ryanodine receptor gene (RYR1); this is expressed in skeletal muscle as a calcium release channel of the sarcoplasm reticulum. In other families, a gene in this location is excluded, but the locations of the genes involved have not yet been defined. We have analysed DNA samples from members of three large British families in whom in vitro *muscle contracture tests for malignant hyperthermia susceptibility have been carried out in accordance with the procedure recommended by the European Malignant Hyperthermia Group. The results presented here strongly suggest that the gene for malignant hyperthermia susceptibility in one or more of these three British families is located in the same region of chromosome 19q, although further work is required to decide whether or not the RYR1 gene itself is causative in these families. As genetic heterogeneity could not be excluded, we cannot yet recommend the use of DNA markers to replace* in vitro *contracture tests in the diagnosis of malignant hyperthermia susceptibility.* (Br. J. Anaesth. 1993; **70**: 70–75)

KEY WORDS
Genetic factors: linkage analysis. Hyperthermia: malignant.

Malignant hyperthermia (MH) is an inherited pharmacogenetic disorder characterized by muscle rigidity and accelerated metabolism, together with associated secondary manifestations in susceptible individuals exposed to triggering agents such as inhalation anaesthetics and depolarizing muscle relaxants [1]. Denborough and co-workers [2] described a pedigree in which clinical MH segregated in an autosomal dominant manner. Development of *in vitro* contracture testing to determine susceptibility to MH [3, 4] has permitted the screening of relatives of probands presenting with clinical MH. Susceptibility is determined currently by the contracture response of living muscle tissue to *in vitro* exposure to halothane and, separately, to caffeine. From 1984, the standard method for these tests is described in the procedure recommended by the European Malignant Hyperthermia Group [5]. This designates patients to be MHS (susceptible), MHE (equivocal) and MHN (normal) according to whether they respond abnormally to both drugs, one drug alone, or neither drug, respectively. Before 1984, patients were characterized as either positive or negative for malignant hyperthermia susceptibility. These family studies have confirmed the autosomal dominant mode of inheritance of MH susceptibility [6, 7]. Recent developments in molecular genetics should enable the mapping of gene(s) responsible for the disorder. This might in turn result in non-invasive methods for the presymptomatic diagnosis of MH susceptibility.

In certain breeds of pig, a similar (but perhaps not identical) disorder has been described [8]. The porcine gene conferring halothane-induced MH susceptibility, *HAL*, is genetically linked to those encoding glucose phosphate isomerase, *GPI*, and the ryanodine receptor, *RYR1* [9, 10], and is probably identical to the last. The human homologues of these loci are linked and lie on the long arm of chromosome 19, known as 19q [11].

We have studied three large British families segregating for MH susceptibility to see if a mutated gene on chromosome 19q may underlie this condition.

METHODS

Families

Patients are referred to the Leeds MH Investigation Unit after a suspected MH anaesthetic reaction. If the proband has survived and is found to be susceptible to malignant hyperthermia, other close relatives are invited to have a diagnostic muscle biopsy. If the proband has died, family studies are initiated with the parents, if possible.

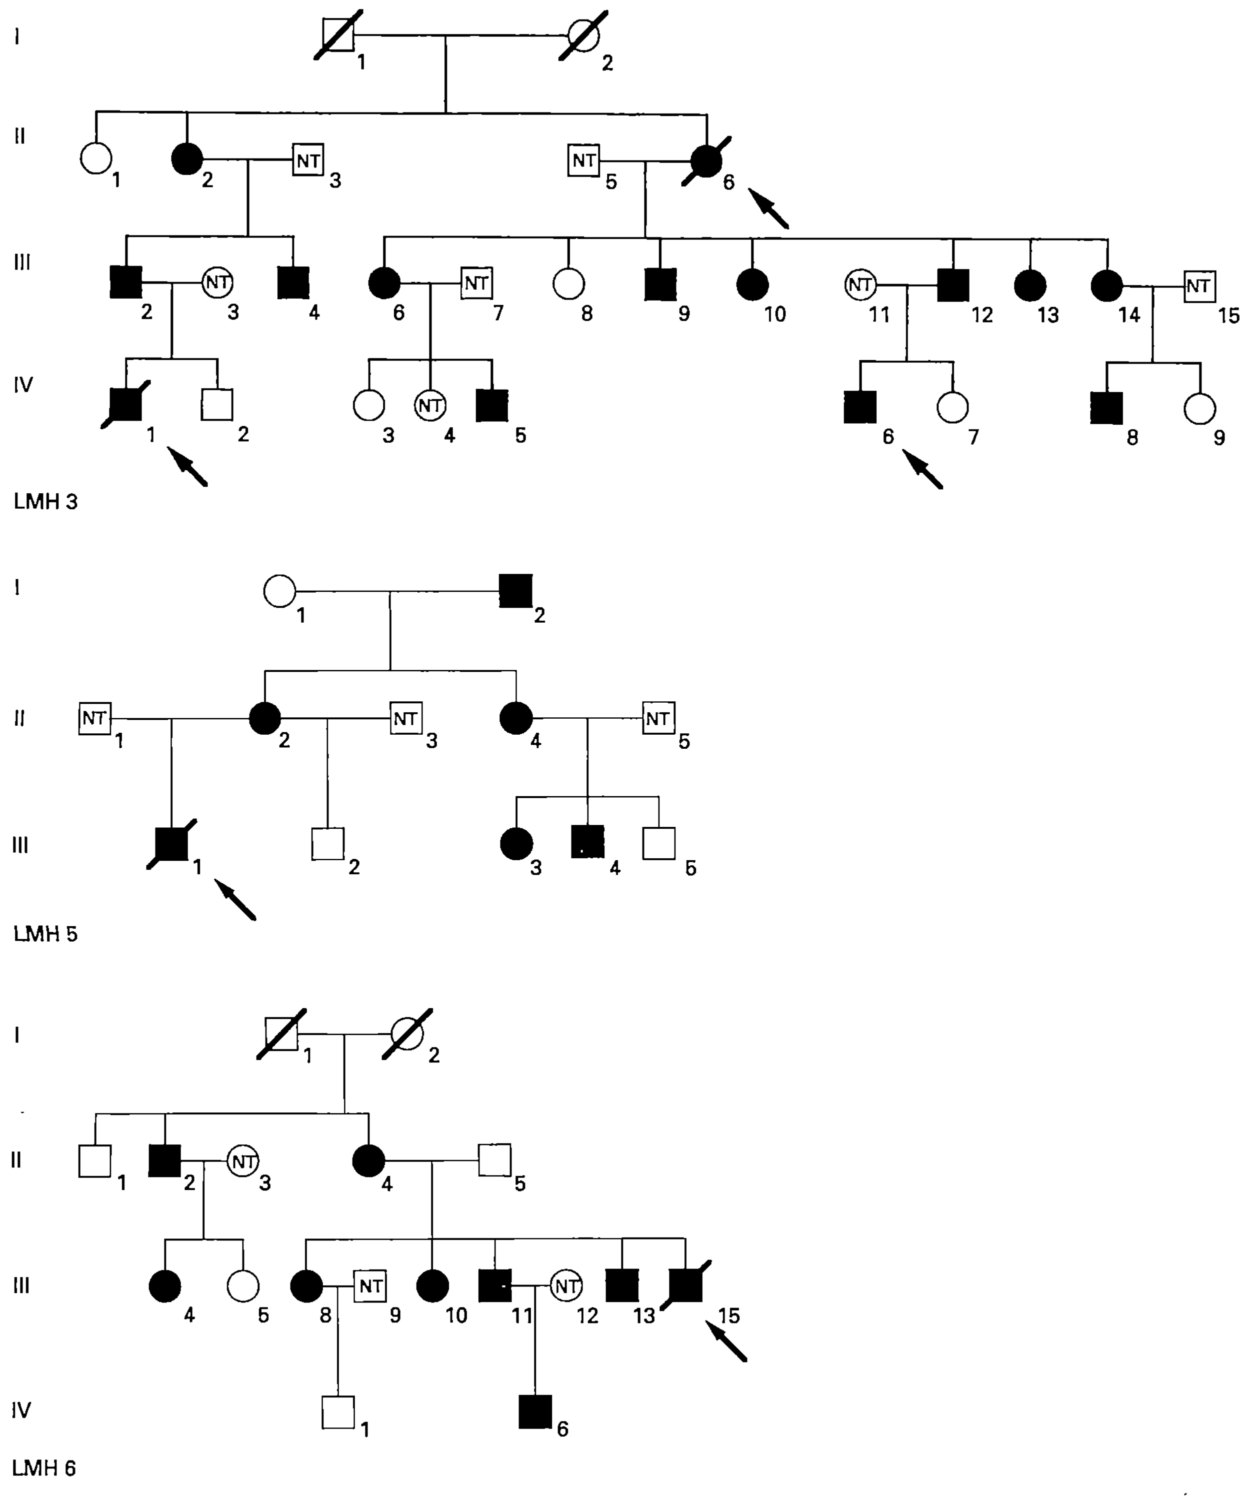

FIG. 1. Pedigrees of three families used for the linkage analysis of susceptibility to malignant hyperthermia. ● = *In vitro* contracture test (IVCT) positive—that is, MHS; ○ = IVCT negative (MHN); NT = not tested with IVCT.

Blood was collected from members of three, large triple-generation families (LMH3, LMH5 and LMH6) which had been studied in this way. The pedigrees of these families are shown in figure 1. These families were selected because at least one member of each had had an episode of fulminant MH, and because the *in vitro* contracture tests in the family members gave results which permit definite diagnosis. In two of these families, the proband had died from MH; in the other family, there were two probands, one of whom died and the other survived.

DNA was extracted from peripheral blood samples using standard methods [12]. Typing of alleles at genetic marker loci was performed as described below, using Southern blotting and microsatellite amplification procedures. The results from these genetic typings were used for linkage analysis.

Southern blot analysis

Southern blots of genomic DNA digested with the appropriate restriction enzyme were hybridized with DNA probes to reveal the restriction fragment length

				3.5	0.44

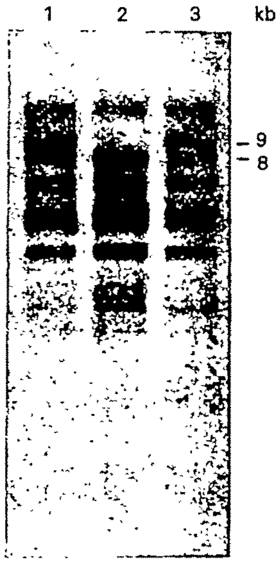

FIG. 2. Restriction fragment length polymorphism detected with probe p4.1, corresponding to locus *D19S7*. Lane 1: Mm heterozygote; lane 2: mm homozygote; lane 3: MM homozygote.

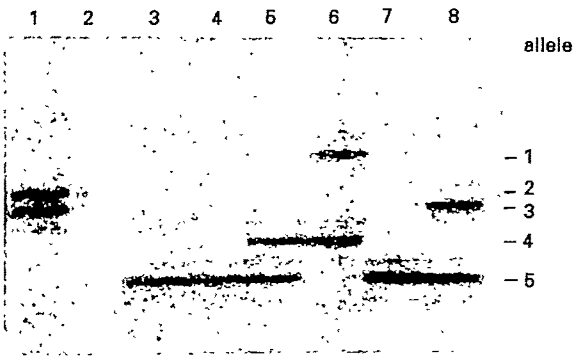

FIG. 3. Hypervariable microsatellite locus *D19S47* revealed using Mfd9 primers. Five bands of different sizes can be seen; any one individual possesses either one (homozygote) or two (heterozygote) of these marker alleles. Lane 1: 2,3 heterozygote; lane 2: no DNA (PCR control); lane 3: 5,5 homozygote; lane 4: 5,5 homozygote; lane 5: 4,5 heterozygote; lane 6: 1,4 heterozygote; lane 7: 5,5 homozygote; lane 8: 3,5 heterozygote.

polymorphisms (RFLP) [13] described in table I. The pattern observed on an autoradiograph showing an RFLP with the probe for D19S7 is shown in figure 2.

Hypervariable microsatellites

The human genome contains large numbers of very simple repeat sequences, such as the bases $(CA)_n$ where n may vary from 5 to about 20. Although their function (if any) is uncertain, they are found through many of the non-coding regions of chromosomes. The length of the repeat unit at any one chromosomal position usually varies from person to person (or chromosome to chromosome), so that typically five or more different lengths of these repeat sequences are present in the population. The consequence of this is that the length of the repeat unit is highly informative as a marker which may be used in the same way as RFLP for following the inheritance of individual chromosomes in family studies. For this reason, hypervariable microsatellite marker loci are being used increasingly in gene mapping and genetic diagnosis [14]. A marker of this type is visualized by amplifying the region containing the simple repeat from unique genomic sequences which have been identified as flanking it on each side, using the polymerase chain reaction. The length of the two repeat units found on the two chromosomes in each individual may then be determined by high resolution gel electrophoresis. Polymerase chain reactions to amplify the hypervariable regions were carried out essentially as described previously [15], except that radiolabelled ^{32}P-deoxycytidine triphosphate (dCTP) was used to label the DNA product. The primer sequences used specifically amplified the hypervariable microsatellite regions of Mfd5 and Mfd9, corresponding to the loci *APOC2* and *D19S47*, respectively. Both markers are known to be located on chromosome 19q [11]. The pattern of bands observed on an autoradiograph corresponding to alleles of the *D19S47* locus is illustrated in figure 3.

Linkage analysis

Linkage analysis was performed using the computer program LINKAGE v5.03 [16]. For the purpose of these linkage analyses, calculations have included the following assumptions in line with the recommendations of the genetics section of the European MH Group: a false negative rate on contracture testing of 2%; a false positive rate on contracture testing of 2%; frequency of the MH susceptibility allele 1 in 10000 in the population (corresponding to an incidence of 1 in 5000).

The LINKAGE program calculates the likelihood of obtaining the observed results with a specified degree of linkage, θ, between the susceptibility gene and the marker locus, compared with the likelihood of obtaining the same results in the absence of linkage. These likelihoods can be calculated for all degrees of recombination, θ, between 0.0 (complete linkage) and 0.5 (no linkage—that is, 50% recombination). By convention, relative likelihoods are expressed in the form of an odds ratio (for example, 10:1) against obtaining the observed linkage by chance. These likelihoods are then reported as logarithms ($\log_{10}$) of the likelihood, and are known as the "lod" (log **odds**) score. In this form, the likelihoods from different families can be combined

simply by adding the lod scores for each (equivalent to multiplying the likelihoods).

A lod score of +3 is generally regarded as sufficient to establish a putative linkage in the absence of previous data; however, a lod score of +2 (corresponding to odds of 100:1) may be regarded as confirming the linkage for subsequent families. A lod score of −2 or less is taken as evidence excluding genetic linkage over the region where it applies around the marker locus because recombination has been found between the disease gene and the marker. Lod scores calculated by the LINKAGE program can be tabulated for each pedigree and each marker for several values of the recombination fraction, θ, from 0.001 (0.1% recombination) up to 0.5.

RESULTS

Results of the *in vitro* contracture tests from members of families LMH3, LMH5 and LMH6 are shown in table II. The results of analysis of the linkage relationships between MH susceptibility and chromosome 19 markers are shown in the form of lod scores in table III. This statistical analysis provides evidence for a chromosome 19q location for the gene determining susceptibility to MH in some or all of these three families.

Close linkage is demonstrated between MH susceptibility and *D19S47*, the maximum lod score of +2.11 being found at a recombination fraction of 0.075. Significant linkage has not, however, been demonstrated in any individual family, possibly because the marker was not fully informative. The MH gene is located more distantly from *APOC2*, with a maximum lod score from all three families of +1.19 at a recombination fraction of 0.20. The region around *APOC2* itself is excluded in family LMH3 (lod score less than −2). Linkage to the region of the marker *D19S7*, which is located much nearer to the centromere of chromosome 19 and the other markers, is excluded for two of the families (LMH3 and LMH6).

DISCUSSION

Genetic linkage of the gene conferring susceptibility to malignant hyperthermia with the region of chromosome 19q close to the gene encoding the ryanodine receptor (*RYR1*) was first reported for Irish [7] and North American [17] families. The ryanodine receptor is a protein which contains a calcium release channel in the sarcoplasmic reticulum of skeletal muscle, so *RYR1* is attractive as a candidate gene for MH susceptibility. There is physiological evidence implicating an abnormality of the ryanodine receptor in both porcine [18] and human [19] MH susceptibility.

It is important to stress that the families in this present study were chosen because the typing of each individual as susceptible or non-susceptible was regarded as firm on the basis of the muscle contracture tests. The results presented here strongly suggest that the gene for MH susceptibility in one or more of these three British families is located in the same region of chromosome 19q. Whether or not *RYR1*, rather than another gene in the same region, is responsible for MH susceptibility in some or all of the families showing linkage to chromosome 19q is the subject of continuing work.

The question of genetic heterogeneity within MH susceptibility must also be examined. Families from North America and Central Europe have been reported which apparently exclude the relevant region of chromosome 19q from linkage with MH susceptibility [20, 21]. Indeed, it is possible that another region may be involved in one or two of the families reported here. Further studies on more families are needed to establish the proportions of families with MH susceptibility which map to chromosome 19 and to other regions of the genome. It also needs to be established if there is any correlation between the degree of sensitivity of the muscle of susceptible individuals to the *in vitro* contracture tests and linkage to chromosome 19. To facilitate progress in answering this question, we suggest that reports in this area include full contracture data, comprising the drug threshold for contracture, the strength of contracture at that threshold and the strength of contracture at 2% halothane (corresponding to 0.44 mmol litre^{-1}) and caffeine 2 mmol litre^{-1}, respectively.

In order to preserve international conformity, we have accepted the linkage analysis parameters for MH agreed by the genetics section of the European Malignant Hyperthermia Group. We think that these confidence limits are conservative when applied to our own data, and believe that this constitutes a suitable safeguard against drawing false conclusions.

Until the questions regarding the genetic heterogeneity of MH are resolved, it is clearly inappropriate to use the linkage of DNA marker loci as a diagnostic test for MH susceptibility in place of muscle contracture testing in a recognized centre.

IN VITRO EFFECT OF EPHEDRINE, ADRENALINE, NORADRENALINE AND ISOPRENALINE ON HALOTHANE-INDUCED CONTRACTURES IN SKELETAL MUSCLE FROM PATIENTS POTENTIALLY SUSCEPTIBLE TO MALIGNANT HYPERTHERMIA

A. URWYLER, K. CENSIER, M. D. SEEBERGER, J. M. ROTHENBÜHLER, M. A. KAUFMANN AND J. DREWE

SUMMARY

We have measured the effects of ephedrine, adrenaline, noradrenaline and isoprenaline on halothane-induced contractures in muscle biopsies from patients potentially susceptible to malignant hyperthermia (MH). At concentrations of 4–24 mmol litre^{-1}*, ephedrine induced* in vitro *contractures in halothane 0.44 mmol litre*$^{-1}$*-prechallenged muscle, whilst adrenaline, noradrenaline and isoprenaline had no effect. There was a shift of the ephedrine concentration–response curve to the left and an increased maximum muscle contracture in the MH susceptible group compared with the MH negative group (*$P < 0.001$*). We conclude that ephedrine increased halothane-induced muscle contractures* in vitro *either by an unknown pharmacological mechanism or by an adrenergic stimulation which was different from those of the other investigated adrenoceptor agonists.* (Br. J. Anaesth. 1993; **70**: 76–79)

KEY WORDS

Hyperthermia: malignant. Muscle: halothane-induced contracture. Sympathetic nervous system, pharmacology: adrenaline, ephedrine, isoprenaline.

Malignant hyperthermia (MH) is characterized clinically by a life-threatening hypermetabolic reaction that is attributed to an underlying muscle disease. Skeletal muscle from MH susceptible (MHS) individuals demonstrates abnormal *in vitro* contractures to halothane, in contrast with muscle bundles from MH negative (MHN) subjects [1, 2]. *In vitro* muscle contractures are characterized by an increase in baseline tension and are related to an increased myoplasmic calcium concentration $[Ca^{2+}]_i$ [3]. There is controversy as to whether or not the sympathetic system is involved primarily or as a secondary response to MH [4], and less is known about the effects of adrenergic agents on muscle metabolism in humans with an acute MH episode. Therefore, we have investigated the effects of different adrenoceptor agonists on halothane-induced muscle contractures *in vitro* in patients potentially susceptible to MH. Some of these results have been published previously in abstract form [5].

PATIENTS AND METHODS

We studied 42 potentially MHS individuals after approval by the University of Basel's Hospital Ethics Committee. All patients gave informed written consent. Biopsies were taken from the vastus medialis muscle under regional anaesthesia with a femoral nerve block using 1.5% mepivacaine 5–7.5 mg kg^{-1}. The muscle tissue was maintained in Krebs–Ringer solution oxygenated with 5% carbon dioxide in oxygen (carbogen) until the experiments were performed. Muscle bundles, approximately 2.5 cm long and 2–3 mm in diameter, were mounted in a test bath containing Krebs–Ringer solution. Temperature was maintained at 37 °C and the bath was bubbled continuously with carbogen. Supramaximal electrical stimulation at 0.2 Hz was used to demonstrate the viability of the muscle bundle. MH susceptibility was evaluated with two halothane and two caffeine tests on four different muscle bundles, and MH diagnosis was made according to a standardized procedure [2, 6].

Surplus muscle bundles were challenged for 10 min with halothane 0.44 mmol litre^{-1} in the test bath, corresponding to 2% in the gas phase, followed by incremental doses of adrenaline ($n = 3$), noradrenaline ($n = 6$), isoprenaline ($n = 3$) or ephedrine ($n = 42$). Twelve bundles were pretreated with incremental doses of ephedrine 4–24 mmol litre^{-1} before the halothane 0.44 mmol litre^{-1} challenge. All drugs were dissolved in Krebs–Ringer solution (pH 7.4) before addition to the test bath. In preliminary experiments, concentrations between 1 nmol litre^{-1} and 1 mmol litre^{-1} of all adrenergic agents studied

Accepted for Publication: July 7, 1992.

did not initiate any muscle contractures [unpublished results], and thus each adrenoceptor agonist was evaluated at greater concentrations: 4, 8, 12, 16 and 24 mmol litre^{-1}. Drug concentrations were maintained for at least 3 min or until a steady state in baseline tension was achieved. Muscle contractures were recorded for each concentration of the various agents. The baseline value just before addition of the first dose of an adrenergic agonist was used as the zero level.

Drugs were obtained from the following commercial sources: halothane from Halocarbon Laboratories, Hackensack, NJ, U.S.A.; pure caffeine from Merck, Darmstadt, Germany; (−)-adrenaline hydrochloride (HCl), (−)-noradrenaline HCl, (−)-isoprenaline HCl, (−)-ephedrine HCl from Sigma Chemical Co., St Louis, MO, U.S.A.

Data analysis

Ephedrine concentration–response curves were calculated by non-linear regression analysis according to the sigmoidal maximum effect model (Hill equation) (SAS, Release 6.03, U.S.A.). Data are presented as mean (SEM) and 95% confidence intervals (95% CI). Statistical analyses were performed using multiple one-sided or two-sided Student's t tests with Bonferroni correction as appropriate. $P < 0.05$ was considered to represent a significant difference between the groups.

RESULTS

Sixteen individuals were classified as MHN, while 26 patients were considered to be clinically MHS (fig. 1). The clinically MHS group consisted of 17 individuals who had abnormal contracture tests to halothane and caffeine challenges and a second group of nine MH equivocal patients (MHEh) with abnormal halothane but normal caffeine contracture tests.

In muscle bundles from 12 patients (MHN: $n = 5$; MHS: $n = 7$), administration of ephedrine before halothane did not produce any contractures. However, when halothane was added to the test bath after pretreatment with ephedrine, all muscle bundles demonstrated contractures (12.6 (3.6) mN (95% CI 2.6–22.6 mN) in the MHN group compared with 43.9 (10.3) mN (95% CI 18.6–69.1 mN) in the MHS group).

After the halothane 0.44 mmol litre^{-1} challenge, there were no muscle contractures in bundles of MHS individuals after addition of adrenaline, noradrenaline or isoprenaline to the test bath, whilst ephedrine induced dose-dependent muscle contractures in all these muscle bundles (table I, fig. 2).

There was a significant shift of the ephedrine concentration–response curve to the left for the MHS group compared with the MHEh and MHN groups (table II, fig. 3). Eight patients had to be excluded for the calculations of EC$_{50}$ and the maximum effect (*E*max), because there were no muscle contractures in response to ephedrine ($n = 4$ in the MHN group) or because *E*max was not achieved in the range of the investigated concentra-

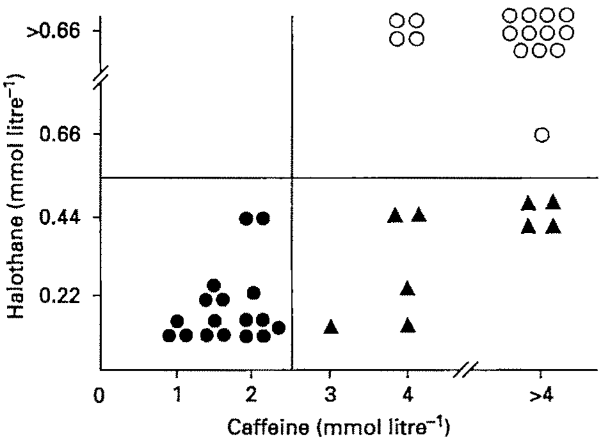

FIG. 1. Classification of 42 patients investigated with *in vitro* muscle contracture tests according to the procedure of the European Malignant Hyperpyrexia Group [2]. For the diagnosis of MH susceptibility the threshold concentrations of halothane and caffeine were used which initiated an *in vitro* muscle contracture ≥ 2 mN. MHN (○) ($n = 16$) = MH negative; MHS (●) ($n = 17$) = MH susceptible (abnormal halothane and abnormal caffeine contracture tests); MHEh (▲) ($n = 9$) = MH equivocal (abnormal halothane but normal caffeine contracture tests).

TABLE I. In vitro *contractures (≥ 2 mN) initiated by various adrenoceptor agonists in 29 muscle bundles from MHS subjects. Each adrenoceptor agonist was evaluated at increasing concentrations (4, 8, 12, 16 and 24 mmol litre^{-1}) in the presence of halothane 0.44 mmol litre^{-1}*

	Number of contractures	Number tested
(−)-Ephedrine	17	17
(−)-Adrenaline	0	3
(−)-Noradrenaline	0	6
(−)-Isoprenaline	0	3
(−)-Ephedrine after (−)-adrenaline	3	3
(−)-Ephedrine after (−)-noradrenaline	6	6
(−)-Ephedrine after (−)-isoprenaline	3	3

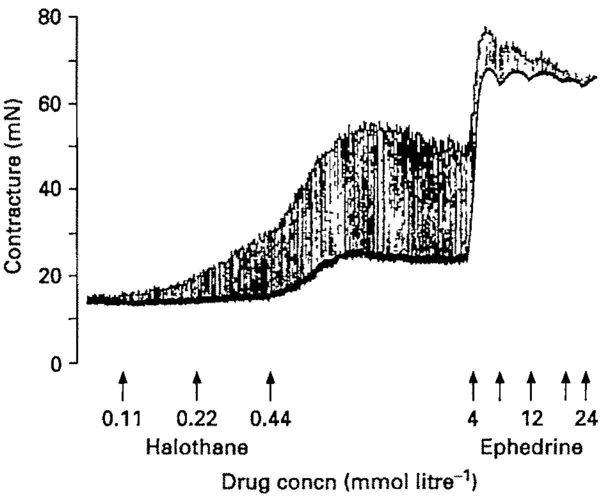

FIG. 2. Representative curve of halothane and ephedrine effects on the *in vitro* muscle contracture of an MHS individual. Contractions were elicited using supramaximal electrical stimulation (0.2 Hz) to prove the viability of the muscle bundle. Halothane and ephedrine were added to the test bath in increasing concentrations as indicated (labels 8 and 16 (mmol litre^{-1}) omitted for ephedrine, for clarity.)

TABLE II. In vitro *effect of ephedrine on halothane-induced muscle contractures (mean (SEM) [95% confidence intervals]). Significant changes (multiple one-sided* t *test with Bonferroni correction):* *P < *0.05 (compared with MHN group);* †P < *0.05 (compared with MHEh group);* ***P < *0.001 (compared with MHN group)*

	n	*E*max (mN)	EC_{50} (mmol litre^{-1})
MHN	12	17 (3.2) [10–24]	11.8 (1.1) [9.3–14]
MHEh	7	20 (3.9) [11–30]	9.4 (1.9) [4.8–14]
MHS	15	29 (4)* [20–38]	4.6 (1)†*** [2.5–6.8]

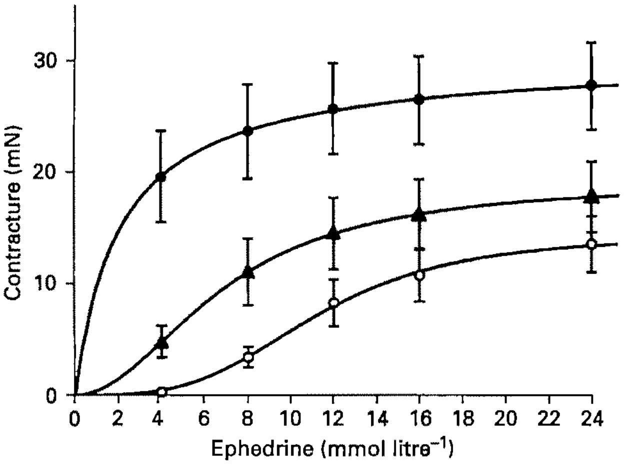

FIG. 3. Mean (SEM) *in vitro* effect of ephedrine on halothane-induced contractures in muscle bundles from patients potentially susceptible to malignant hyperthermia. MHS (●) ($n = 17$) = MH susceptible (abnormal halothane and caffeine contracture); MHEh (▲) ($n = 9$) = MH equivocal (abnormal halothane but normal caffeine contracture); MHN (○) ($n = 16$) = MH negative.

tions ($n = 1$ in the MHN group, $n = 2$ in the MHEh group and $n = 1$ in the MHS group).

DISCUSSION

In this study, ephedrine 4–24 mmol litre^{-1} increased halothane-induced *in vitro* muscle contractures, whilst adrenaline, noradrenaline and isoprenaline had no effect. There was a statistically significant shift of the ephedrine concentration–response curve to the left in the MHS group compared with the MHN group. These data suggest the possibility that ephedrine increased muscle metabolism *in vitro*. However, the exact mechanism of the *in vitro* effect of ephedrine on skeletal muscle is speculative.

In general, ephedrine is considered to have direct and indirect sympathomimetic effects, but the exact pharmacological mechanism(s) is not known [7]. Because inositol 1,4,5-triphosphate (IP_3) has been found to be increased in muscle tissue from MHS pigs and MHS humans [8, 9], one could speculate that ephedrine might increase intracellular IP_3 concentrations and thereby increase halothane-induced muscle contractures. Alternatively, or in addition to IP_3, it may be that ephedrine effects are mediated indirectly by cyclic AMP, comparable to the effects of theophylline or caffeine on skeletal muscle *in vitro* [10]. Recent work has shown the possible involvement of a mutation of the ryanodine receptor gene as the primary defect in MHS individuals [11, 12]. Therefore, it may be interesting to determine if ephedrine interacts directly or indirectly with the ryanodine receptor.

If ephedrine initiates muscle contractures by an adrenergic effect, this mechanism must differ from classical adrenergic stimulation because adrenaline, noradrenaline and isoprenaline did not have similar effects. Little is known about the adrenergic effects on halothane-induced *in vitro* muscle contractures. To our knowledge, only noradrenaline in porcine skeletal muscle [13] and salbutamol, a $beta_2$-adrenoceptor agonist, in human skeletal muscle have been investigated [14]. Both adrenoceptor agonists did not potentiate halothane-induced muscle contractures. Our study provides additional evidence that the sympathomimetic system does not initiate MH primarily [15, 16], as we did not find any contractures in muscle bundles from MHS individuals after challenges with adrenaline or noradrenaline.

The clinical relevance of *in vitro* muscle investigations, as performed in the present study, is unclear, as we used ephedrine in concentrations of 4–24 mmol litre^{-1}, 1000–2000-fold greater than clinically relevant plasma concentrations. However, these large concentrations of ephedrine *in vitro* could reflect the requirement that effective tissue concentrations can be achieved by diffusion, in contrast to the situation *in vivo* when ephedrine is brought into muscle tissue by capillary circulation. Clinically, ephedrine increases energy expenditure [17, 18] and has been proposed as a thermogenic drug for the treatment of obesity [19] and cyclical hypothermia [20] or for the improvement of cold tolerance [21]. Leg oxygen consumption increased 60% after ephedrine administration and it was speculated that 50% of the increase in oxygen consumption induced by ephedrine may take place in skeletal muscle [17]. In anaesthetics, ephedrine is used for vasopressor therapy in hypotension as a result of regional or general anaesthesia [21]. To our knowledge, there are no clinical data suggesting ephedrine as a MH trigger. However, these data suggest the use of alternative adrenergic drugs if cardiovascular instability is associated with a hypermetabolic state in MHS individuals.

REVIEW ARTICLE

THE ROLE OF RECOMBINANT GROWTH FACTORS IN TRANSFUSION MEDICINE

L. T. GOODNOUGH

There is renewed interest in alternatives to blood transfusion. The changing environment of transfusion medicine includes increased awareness of patients and physicians as to the problems of safety of blood, desirability of blood conservation, and informed consent before elective blood transfusion [29]. For example, physicians may be more conservative in respect of the PCV at which transfusion is indicated [14] in anaemic medical and surgical patients [56]. This includes orthopaedic surgery patients who choose to predeposit autologous blood [55]. Similarly, the use of blood and blood components has been reduced substantially by the use of strategies for blood conservation during surgery. A combination of techniques such as preoperative autologous blood donation, acute haemodilution, use of non-blood pump prime, intra- and postoperative autologous blood salvage and reinfusion and, most importantly, acceptance of normovolaemic anaemia after operation, have resulted in a reduction in red blood cell transfusion in the United States [52].

In addition to these methods of blood conservation, recombinant growth factors now show promise in reducing or eliminating the requirement for homologous blood components, when used in combination with other blood conservation methods in a variety of clinical circumstances. This review considers recent developments in this area, including the haematopoietic growth factor recombinant human erythropoietin (rHuEPO), and the myeloid growth factors granulocyte colony stimulating factor (G-CSF) and granulocyte–macrophage colony stimulating factor (GM-CSF).

STIMULATION OF HAEMATOPOIESIS: ERYTHROPOIETIN

The development of rHuEPO, from identification as the hormone regulating erythropoiesis [7], to purification and identification [41] of human urinary erythropoietin, and subsequent cloning, expression and characterization as a recombinant product [6, 36, 53], has occurred in the relatively brief period of only 32 years (1953–1985). Furthermore, the extension of this advance to direct use in the clinical treatment of anaemias has occurred within the very short interval of only 2 years.

Erythropoietin is a circulating plasma polypeptide comprising 166 amino acids; it is heavily glycosylated, with a molecular weight of approximately 34000. Purified rHuEPO has an amino acid sequence identical to that of human urinary erythropoietin [41]. The natural and urinary hormones are indistinguishable from rHuEPO on the basis of all immunological and biological comparisons performed to date, the carbohydrate composition and both immunological and biological properties. rHuEPO is more than 98% pure, with a specific activity of more than 100000 u/mg of hormone [6]. To date, there has not been a report of a patient who has developed alloantibodies to rHuEPO. From its initial use in patients with anaemia caused by renal failure, the potential uses of rHuEPO have expanded to many areas of surgical and medical anaemias.

Erythropoietin therapy in elective surgery

In elective surgery, preoperative autologous blood donation represents an attractive alternative to homologous blood transfusion. Potential candidates for autologous blood donation before surgery include any patient undergoing a procedure for which blood type and crossmatch was requested. The underutilization of autologous donation before elective surgery, demonstrated previously [53], can be improved with a co-ordinated programme involving hospital blood bank, information services and clinicians [35]. Nonetheless, a previous study has shown that orthopaedic patients predeposit insufficient autologous blood to obviate subsequent exposure to homologous blood [31]. At the University Hospitals of Cleveland, we have audited the homologous blood transfusion needs in elective orthopaedic surgical patients who did not become autologous blood donors and have shown that a significant percentage of patients require substantial amounts of blood transfusion (table I) [24]. For example, 45% of elective hip replacements and 15% of elective knee operations required administration of ⩾4 u of homologous blood. Potential problems limiting the procurement of autologous blood sufficient to meet these significant blood transfusion needs before orthopaedic surgery include: underordering by surgical staff; limitations of the storage interval; erythropoietic response to phlebotomy.

Procedure	Blood transfused (u)							
	0	1	2	3	4	5	6	≥ 7
Hip ($n = 275$)	19 (6.9)	18 (6.5)	67 (24)	48 (18)	60 (22)	25 (9.1)	16 (5.8)	22 (8.0)
Knee ($n = 223$)	62 (28)	16 (7.2)	78 (35)	35 (16)	12 (5.4)	10 (4.5)	3 (1.3)	7 (3.1)
Spine ($n = 450$)	289 (64)	26 (5.7)	58 (13)	29 (6.4)	25 (5.5)	5 (1.1)	10 (2.2)	8 (1.8)
Misc. ($n = 279$)	214 (77)	4 (1.4)	25 (9)	10 (3.6)	11 (3.9)	6 (2.2)	3 (1.1)	6 (2.2)

A continuing medical education (CME) programme can correct the problem of underordering. Subsequent exposure to homologous blood in patients who successfully stored the amount of autologous blood requested by orthopaedic surgeons was reduced to 19 (13 %) of 145 patients in one study [31]. CME had no impact, however, on the effective storage interval (the time interval from day of surgical scheduling until date of surgery) during which blood can be collected for elective surgery. The mean storage interval before and after a CME programme has been shown to remain at 21 days [32], despite the ability to procure and store liquid blood up to a maximum of 42 days before transfusion. Exposure to homologous blood has been demonstrated to be unrelated to surgical underordering of autologous blood. Of 58 patients who were asked to donate ≥ 4 u, 23 (40 %) were deferred and nine of 23 (39 %) subsequently received homologous blood, compared with only seven of 117 (6 %) patients deferred when asked to donate ≤ 3 u; but four of these seven (57 %) subsequently received homologous blood. It has thus been demonstrated that when an autologous donation programme is accompanied by a CME programme, exposure to homologous blood is related to the donor deferral rate, rather than surgical underordering or inappropriate transfusion.

In the studies described above, the erythropoietin response to mild anaemia (PCV ≥ 33 %) was inadequate to allow autologous donation of the requested number of units in 30 of 175 patients and in 23 of 58 patients asked to store ≥ 4 u. Thus erythropoietic response to phlebotomy is the third limiting factor in the procurement of autologous blood sufficient to minimize the need for subsequent exposure to homologous blood. The American Association of Blood Banks has guidelines for elective, preoperative, autologous blood donation that include a haemoglobin concentration of not less than 11 g dl^{-1} or a PCV of not less than 33 %, and phlebotomy no more frequent than every 3 days and not within 72 h of surgery [50]. Previous studies on the relationship between decreasing packed red blood cell volume and endogenous immunoreactive plasma erythropoietin have indicated that this relationship is linear at haemoglobin concentrations less than approximately 11.5 g dl^{-1} [10]; at greater values there is no linear relationship, indicating that significant losses of red cell volume are required to stimulate endogenous erythropoietin. Studies have confirmed that the mild, iatrogenic anaemia induced by serial phlebotomy in autologous blood donors is not accompanied by an endogenous erythropoietin response adequate to stimulate compensatory bone marrow erythropoiesis [21, 34]. An analysis of autologous blood showed a linear decrease in mean red cell volume (donor PCV % multiplied by blood volume donated) with sequential donations, demonstrating an absence of compensatory erythropoiesis under normal blood donation conditions (fig. 1) [20]. When the red cell volumes of autologous blood were compared with male and female homologous blood, 20 % of autologous blood had red cell volumes less than the lower 95 % confidence interval for homologous blood units [20]. Thus not only do autologous blood donors have difficulty in predonating the amount of blood requested for surgery, but the oxygen-carrying capacity of sequential units of autologous blood donated is significantly less than that of homologous blood.

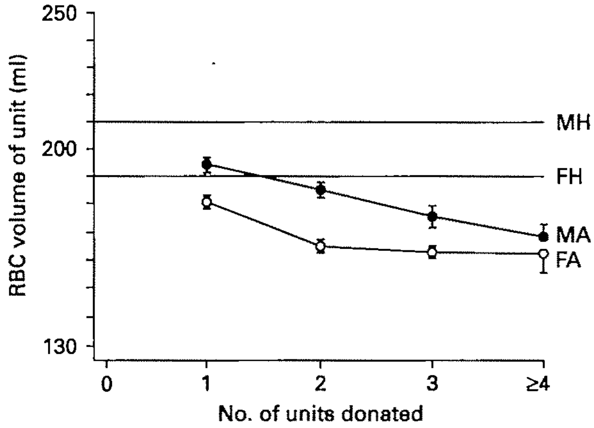

FIG. 1. Mean red blood cell (RBC) mass of blood units donated by 300 homologous donors compared with 79 autologous donors. Red cell mass was determined by multiplying blood volume donated times donation PCV (%). M = Male; F = female; H = homologous; A = autologous. (From reference [20], with permission).

The effectiveness of autologous blood donation in conserving homologous blood donation has been demonstrated for both open heart surgery [42] and orthopaedic surgery [28]. Figure 2 illustrates the extent of homologous blood transfusion in orthopaedic surgery, both for patients who were autologous blood donors and for non-autologous patients [27]. The likelihood of homologous blood transfusion declined for both groups over a 3-year interval, suggesting an increase in the threshold for transfusion; during this period, the mean number of autologous blood units donated by patients did not change, and there were no additional conservation techniques such as intra- or postoperative autologous blood salvage. Table II illustrates the homologous

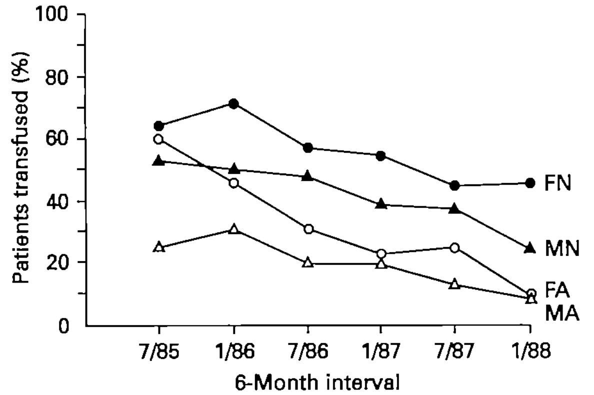

FIG. 2. Percentage of patients receiving homologous blood transfusion in autologous (A) compared with nonautologous (N) groups. The percentage of patients transfused with homologous blood declined from 60% for male (M) and 43% for female (F) nonautologous blood patients and from 35% (M) and 60% (F) in autologous donors in the first 6-month interval to 17% (all groups) in the last 6 months. (From reference [27], with permission.)

TABLE II. *Number of patients who had predonated autologous blood at the University Hospitals of Cleveland in the period July 1, 1985–June 30, 1988 and subsequently received homologous blood transfusion in elective orthopaedic surgery. (From reference [18], with permission)*

	Blood transfused (u)						
Procedure	1	2	3	4	5	6	Total
Hip ($n = 152$)	0	1	5	9	11	4	30

Total ($n = 430$)	0	3	10	24	22	13	72 (16.7%)

blood needs of autologous blood donors in hip, knee and spinal surgery [18]. No patient received only 1 u of homologous blood, again demonstrating a conservative approach by the physician. However, several patients required 3–6 u of homologous blood in addition to the autologous blood units donated. A significant, preoperative, increased production of red cell volume would be necessary in order to generate the volume of autologous blood equivalent to the subsequent requirement for homologous blood in these patients.

These results suggested that treatment with rHuEPO would prevent the development of anaemia in these patients and increase the volume of autologous blood that could be collected before surgery. This was confirmed in a randomized, double-blind, placebo-controlled, multicentre study to determine if erythropoietin therapy could facilitate preoperative autologous blood donation [26]. Patients receiving erythropoietin 600 μg kg^{-1} i.v. twice weekly donated a 41% greater red blood cell volume compared with placebo-treated patients (fig. 3). Analysis of changes in PCV in these patients suggested that the equivalent of approximately 4 u of blood could be generated by this method [19] thus providing a rationale for the elimination of homologous blood transfusion.

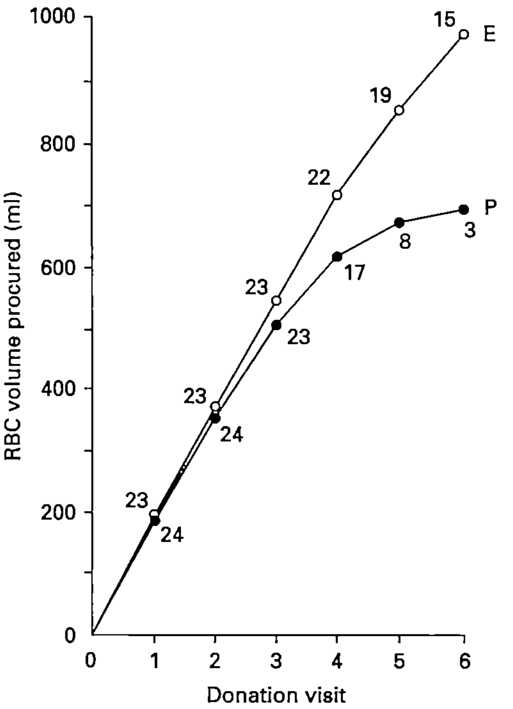

FIG. 3. Cumulative red blood cell (RBC) volume procured per patient. Number of patients at each donation is indicated. Mean cumulative interval (days) for each visit: visit 2 = 3.5; visit 3 = 7.2; visit 4 = 10.6; visit 5 = 14.2; visit 6 = 17.6. E = Erythropoietin; P = placebo. (From reference [26], with permission.)

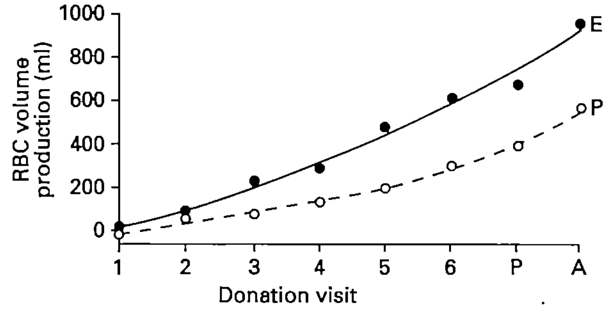

FIG. 4. Red blood cell (RBC) volume before operation during autologous blood donation, in 24 placebo- (○) and 23 erythropoietin- (●) treated patients. Data points represent calculated total volume of RBC (both *in vivo* and *ex vivo*) at donation visits 1–6, post-study visit (P) and at admission to hospital (A). The time required to expand RBC by 200 ml (equivalent to homologous blood 1 u [26]) can be derived for any preoperative interval. E = Erythropoietin; P = placebo.

Further analysis of preoperative red blood cell production (taking into account both *in vivo* and *ex vivo* (stored) red blood cell volumes) indicated that patients who underwent aggressive autologous blood phlebotomy did have a significant (27%) preoperative expansion of red blood cell volume (fig. 4), together with accelerated erythropoiesis at the time of surgery [25]. However, the increase (47%) observed in patients treated with erythropoietin was significantly greater. The major difference in red blood cell production between the placebo and erythropoietin groups occurred early in the collection period; by the time of surgery, there may have been an endogenous erythropoietin effect in the placebo patients sufficient to have diminished the differences between groups [33]. This result was undoubtedly dependent on the attempted removal of blood at the rate of 2 u per week, but not all patients can tolerate such a schedule [4]. For some, such as patients undergoing coronary artery bypass graft surgery, the limiting factor may be the loss of oxygen-carrying capacity, with a PCV of about 30 % [23]. As the increased erythropoiesis may be attributed to the drug rather than to frequent phlebotomy in erythropoietin-treated patients, more modest autologous blood procurement, coupled with administration of erythropoietin, may be preferable [4, 24] in patients unsuited for frequent autologous phlebotomy. Our analysis of preoperative red blood cell production in erythropoietin-treated patients indicates that the autologous blood equivalent of nearly 5 u of homologous blood may be generated by this method [25]. Clinical trials to demonstrate this are in progress in elective orthopaedic and elective coronary artery bypass surgery [19].

This analysis indicates that, for surgical procedures associated with significant blood loss requiring large transfusion needs (e.g. blood $\geqslant$ 4 u), an active programme of procurement of autologous blood is necessary in order to minimize exposure to homologous blood. The value of erythropoietin would be not only to facilitate procurement of autologous blood, but also to prevent the anaemia associated with blood donation in individuals who may have medical risks and poor tolerance for anaemia, frequent phlebotomy, or both [4, 24, 25, 33].

Prudent use of erythropoietin suggests that this agent should be administered in relation to actual blood losses arising from either autologous blood donation or surgical bleeding, in order to avoid the potential complications of polycythaemia and increased blood viscosity [44]. Its use to correct preoperative anaemia should, ideally, be coupled with procurement of autologous blood when the PCV exceeds 33 % [50], not only for these safety concerns, but also to enhance the effectiveness of this therapy in reducing homologous blood transfusion; most blood transfusion in coronary artery bypass surgery, for example, is given on the day of operation and this could be avoided if autologous blood were available before operation [30]. Clinical trials which use exposure to homologous blood as an outcome indicator are currently in progress. Finally, the optimal dose, route and interval of administration for erythropoietin therapy have yet to be established and are the object of current studies [22], the results of which may fulfil the promise of erythropoietin as a new tool in blood conservation as an alternative to homologous blood transfusion in elective surgery [29].

Non-elective surgery

Recombinant erythropoietin also has potential application in patients undergoing non-elective surgical procedures. rHuEPO has been shown to elicit a reticulocyte response within 2.7–3.5 days of administration and a PCV response within 7 days during blood loss in humans [26] and after blood loss in animals [37]. A recent report demonstrated the benefit of rHuEPO therapy in Jehovah's Witnesses undergoing cardiac surgery [16]. Thus pharmacological approaches to blood conservation in the perioperative setting may be expected to have important effects in reducing exposure to homologous blood. A clinical study is in progress to determine the efficacy of perisurgical rHuEPO in open heart surgery [22].

Renal insufficiency

For anaemias related to medical illness, rHuEPO therapy has been shown to be effective and is currently approved for use in the anaemia of chronic renal insufficiency [11, 12, 38]. The effects of dose and duration of therapy of rHuEPO on the rate of increase in PCV have been well described in this population. Adverse effects (thrombosis, accelerated hypertension, seizures) initially associated with the use of rHuEPO in this patient population are related to the excessively rapid correction of anaemia associated with larger doses of rHuEPO [44]; the dose in renal insufficiency has therefore been recommended as 50 $\mu g\ kg^{-1}$ s.c. three times weekly.

Anaemia associated with AIDS

rHuEPO has also been approved recently for treatment of the anaemia associated with AIDS. A prospective, randomized clinical trial demonstrated improvement of anaemia and reduction of transfusion requirements in patients undergoing zidovudine therapy, in whom initial serum concentrations of erythropoietin were less than 500 $\mu g\ ml^{-1}$ [13]. Six of 15 such patients were reported to develop anaemia requiring transfusion (haemoglobin concentration less than 10.0 $g\ dl^{-1}$) within a mean of 6 weeks of beginning zidovudine therapy, despite a nine-fold increase in endogenous erythropoietin concentrations [54]. As approximately 50 % of AIDS patients receiving zidovudine therapy have an anaemia associated with "lower" erythropoietin responses ($< 500\ \mu g\ ml^{-1}$) and zidovudine has been demonstrated recently to be useful in the treatment of paediatric AIDS patients [39], it is anticipated that rHuEPO therapy may be useful in this syndrome.

Other applications

Other possible applications for recombinant erythropoietin are under investigation for the treatment of the anaemia of chronic disease. Studies of endogenous serum concentrations of erythropoietin in patients with anaemia associated with cancer [40], chronic inflammatory disease [3] and AIDS [49] have shown that these diseases have erythropoietin responses inadequate for the degree of anaemia compared with patients with iron-deficient anaemia. Studies of anaemic patients with rheumatoid arthritis (an example of a relatively homogeneous patient group with chronic inflammation) have shown that rHuEPO therapy may be effective both for these patients [43] and in the anaemia of AIDS patients with "lower" erythropoietin responses [13]. Thus pharmacological doses of rHuEPO may be effective for anaemia previously thought to be attributable to environmentally related bone marrow factors rather than inadequate endogenous erythropoietin responses [8]. In addition to the anaemia of chronic inflammation, other potential applications of rHuEPO include anaemia related to cancer treated either without chemotherapy or with chemotherapy (in particular cis-platinum containing regimens, because of their nephrotoxic effects) [40].

rHuEPO may also be useful in the treatment of the anaemia of prematurity. For unexplained reasons, preterm infants may be unable to have an appropriate erythropoietic response in the face of a declining haemoglobin concentration [51]. Growing preterm infants have been demonstrated to have large numbers of circulating progenitor cells that are committed to erythroid differentiation; infant blood contains adequate numbers of responsive colonies of burst forming units-erythroid in *in vitro* culture systems [47]. Recent studies have demonstrated that bone marrow erythroid progenitor colonies are similarly responsive to recombinant erythropoietin in growing preterm infants with the anaemia of prematurity [45]. Thus the need for multiple donor transfusions of a specialized product such as cytomegalovirus-negative blood may be reduced or eliminated by rHuEPO therapy. Clinical trials to date have failed to demonstrate reduction of blood transfusion needs with rHuEPO in the neonate [46]; clinical trials using larger doses of rHuEPO are in progress.

Finally, erythropoietin responses in patients with sickle cell anaemia are known to be attenuated, with increases in serum concentrations of erythropoietin occurring only with haemoglobin concentrations of less than 9 g dl^{-1} [48]. Animal (baboon) studies have indicated that rHuEPO may stimulate a selective increase in percentage of fetal haemoglobin [1], so that rHuEPO therapy may have a potential for reducing the morbidity and frequency of the complications of intravascular sickling, such as vaso-occlusive crises. However, a trial of rHuEPO therapy accompanied by hypoxyurea therapy in patients with sickle cell anaemia failed to show any reduction in vaso-occlusive crises [17]. (For a more complete discussion of the structure and function of erythropoietin and of animal and clinical studies, the reader is referred to an excellent recent review [9].)

STIMULATION OF NON-ERYTHROID CELL LINES: COLONY STIMULATING FACTORS

The colony-stimulating factors (CSF) are a class of glycoprotein hormones that regulate the production and function of myeloid blood cells. Five of these factors—granulocyte–macrophage colony-stimulating factor (GM-CSF), granulocyte colony-stimulating factor (G-CSF), macrophage colony-stimulating factor (M-CSF), interleukin-3 (IL-3) and stem cell factor—have been cloned and the biosynthetic (recombinant) products are undergoing clinical trials. G-CSF and GM-CSF have been approved for use commercially and have important applications in the treatment or prevention, or both, of chemotherapy-induced neutropenia and in the treatment of cytopenias associated with diseases involving the bone marrow (myelodysplastic syndromes, aplastic anaemia, lymphoproliferative diseases, and congenital and idiopathic neutropenias). The rapidly evolving knowledge of this subject is expected to have significant implications for platelet and granulocyte transfusion needs in paediatric patients undergoing solid tumour and leukaemia chemotherapy or bone marrow transplantation, in HIV-infected patients undergoing myelosuppressive therapy, and in patients with congenital and idiopathic neutropenias.

GM-CSF

GM-CSF is a regulatory protein that stimulates proliferation, differentiation and maturation of myeloid haematopoietic precursors, including neutrophils, monocytes and eosinophils. In doses of less than 15 $\mu g\ kg^{-1}\ day^{-1}$, GM-CSF is tolerated well, but after larger doses patients begin to exhibit some toxicity, including bone pain, myalgia and rash. Studies of GM-CSF have shown benefit to patients undergoing autologous bone marrow transplantation, with accelerated recovery of neutrophil counts to more than 500 μl^{-1} within 14 days of transplant [2]. On the basis of subsequent randomized clinical trials of GM-CSF in patients with lymphoma undergoing autologous bone marrow transplantation, GM-CSF has recently been approved for commercial use. Extension of the use of this agent is anticipated in paediatric patients with chemotherapy-induced neutropenia, AIDS-induced neutropenia, aplastic anaemia and haematological malignancies (such as myelodysplastic syndromes and hairy cell leukaemia) [2].

G-CSF

G-CSF and GM-CSF differ in the spectrum of cells that bear their receptors, indicating that the clinical effects of these agents also probably differ. G-CSF exerts its strongest effects on granulocyte precursors, without exhibiting much influence on platelets or macrophages. As some of the toxicities associated with GM-CSF may be caused by activation of eosinophils and macrophages, the use of G-CSF may confer some advantage in a lower prevalence of side effects. Clinical studies of G-CSF in patients undergoing solid-tumour chemotherapy-induced neutropenia have shown that G-CSF decreased the extent and duration of neutropenia [15]. On the basis of subsequent randomized clinical trials of G-CSF in patients undergoing chemotherapy for solid tumours, G-CSF has been approved recently for commercial use. It is anticipated that use of this agent will be extended to paediatric patients with congenital agranulocytosis, cyclic neutropenia and HIV infection [2].

Other colony stimulating factors

Several haematopoietic growth factors, including GM-CSF, IL-3 and IL-6, are known to stimulate human megakaryocytopoiesis [5]. Further research and development of these growth factors and of stem cell colony-stimulating factor can be anticipated to have significant consequences for the platelet transfusion needs of patients, particularly in the areas of solid-tumour chemotherapy and bone marrow transplantation, and in the treatment of the leukaemias. Haematopoietic growth factors may be used in combination in clinical circumstances to achieve significant reductions in requirements for red blood cell and platelet transfusion support, and in morbidity and mortality caused by complications of infections.

SHORT COMMUNICATIONS

INTRA-ARTICULAR MORPHINE FOR PAIN RELIEF AFTER ANTERIOR CRUCIATE LIGAMENT REPAIR

G. P. JOSHI, S. M. McCARROLL, O. H. BRADY, B. J. HURSON AND G. WALSH

SUMMARY

We have performed a randomized, double-blind controlled study in patients undergoing elective anterior cruciate ligament repair, to assess the effect of intra-articular morphine on postoperative pain. The morphine group ($n = 11$*) received morphine 5 mg in saline 25 ml and the control group (*$n = 9$*), saline 25 ml intra-articularly. Patients in the morphine group had significantly smaller pain scores throughout the 24-h postoperative period compared with those in the control group (*$P < 0.05$*). There was less requirement for supplementary analgesics in the morphine group.* (Br. J. Anaesth. 1993; **70**: 87–88)

KEY WORDS

Analgesia, postoperative. Analgesics: intra-articular morphine. Surgery: orthopaedic.

Reconstruction of the anterior cruciate ligament (ACL) of the knee is associated with a significant degree of postoperative pain. Effective analgesia can be obtained with the use of opioids by continuous extradural infusion or by patient-controlled analgesia (PCA). However, these techniques are not without significant side effects [1, 2] and they also require expensive equipment and monitoring.

Intra-articular opioids have been shown to provide high quality analgesia of long duration in patients undergoing arthroscopic procedures of the knee [3, 4]. The analgesia is mediated via a local action within the knee joint. However, the possibility that intra-articular opioids may provide postoperative analgesia in patients undergoing ACL reconstruction surgery has not been investigated and the aim of our study was to examine this.

METHODS AND RESULTS

After obtaining approval from the local Institutional Ethics Committee, we studied 20 consecutive patients (ASA I) undergoing elective ACL repair; all gave informed consent. In each case, the ACL repair was performed by the same surgeon using the same surgical technique.

Patients were premedicated with diazepam 0.15 mg kg^{-1} orally 2 h before surgery. Before premedication, patients were instructed in the use of a 10-cm visual analogue scale (VAS) with 0 and 10 labelled as "no pain" and "worst pain imaginable", respectively.

Anaesthesia was standardized: induction was with a sleep dose of thiopentone and fentanyl 2 μg kg^{-1} and anaesthesia was maintained with isoflurane and 70% nitrous oxide in oxygen. Tracheal intubation was facilitated with vecuronium and ventilation controlled mechanically. Monitoring included ECG, non-invasive arterial pressure, pulse oximetry and end-tidal carbon dioxide measurements. Residual neuromuscular block at the end of the surgery was antagonized with a mixture of neostigmine and glycopyrronium. At the conclusion of surgery, the patients were allocated randomly to two groups. Patients in the morphine group received preservative free morphine 5 mg in saline 25 ml, while those in the control group received normal saline 25 ml, both intra-articularly. The solution was injected after the knee joint was sealed and the tourniquet was released 10 min after the injection.

In the recovery room, after the patient's emergence from anaesthesia, an observer blinded to the agent injected recorded the VAS at 1, 2, 4, 8 and 24 h after operation. Patients who were asleep at the time of evaluation had no VAS recorded. Patients who complained of pain in the recovery room received papaveretum 2.5–5 mg i.v. every 5 min until the pain was controlled. On return to the ward, supplementary analgesia (papaveretum 0.2 mg kg^{-1} i.m.) was available on request. The severity (VAS) and the time of onset of pain were recorded by a blinded observer at the time of administration of analgesia. Patients were interviewed 24 h after operation. Results were analysed using the unpaired t test and the Mann–Whitney U test.

Of the 20 patients admitted to the study, 11 received intra-articular morphine and nine received saline injections. The two groups were similar in age, sex, weight, duration of surgery and amount of fentanyl administered during operation. The VAS scores in the morphine group were significantly ($P < 0.05$) smaller at all times as compared with the

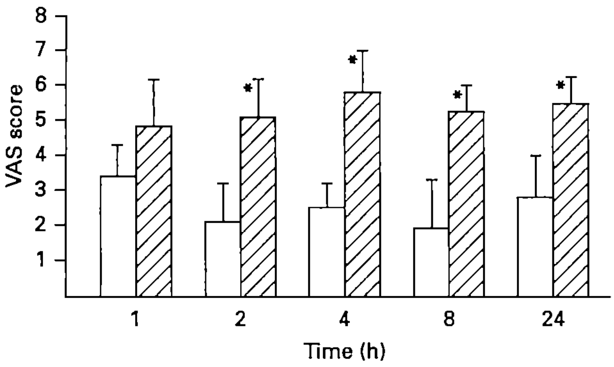

FIG. 1. Visual analogue scale (VAS) scores (mean, SEM) after the ACL repair in patients who received intra-articular morphine and saline. *Statistically significant difference between groups ($P < 0.05$). □ = Morphine group; ▨ = saline group (control).

control group (fig. 1). One patient in the study group required no analgesics and recorded VAS < 6 throughout the study. Patients in the morphine group required less papaveretum at all times. The mean (SEM) total requirement for papaveretum over the 24-h period was 52.7 (14.0) mg in the morphine group and 88.9 (17.6) mg in the control group ($P < 0.05$).

COMMENT

We have found that the use of intra-articular morphine in patients undergoing reconstructive surgery of the anterior cruciate ligament reduced the severity of postoperative pain significantly. Patients not only recorded significantly smaller pain scores, but also required less systemic analgesic.

Although the quality of analgesia overall was better and supplementary requirement of analgesics was reduced, there was a wide variation in pain scores and in analgesic requirements in the morphine group. One patient did not require any supplementary analgesia during the study period; this 24-yr-old female weighed 51 kg. The possibility arises that a larger dose or larger volume, or both, would be more effective in larger patients, suggesting that dose–response and volume–response relationships should be investigated. The dose and volume of the morphine used in this study were based on our previous experience with intra-articular morphine in arthroscopic knee surgery [3]. As patients who have ACL repair have the knee drained after operation, there is the possibility that a volume larger than 25 ml could be injected safely and may prove more effective. The other important component of this technique is to ensure that the tourniquet is kept inflated for at least 10 min after the intra-articular injection [3].

Other techniques used to relieve postoperative pain after ACL repair include continuous extradural infusion and i.v. PCA. However, these techniques are associated with side effects such as nausea, vomiting, pruritis and urinary retention [1]. Respiratory depression [5] and neurological damage, although rare, may also occur after extradural opioids. The incidence of urinary retention after extradural opioids in volunteers and patients varies from 0 to 90% [6]. As most patients undergoing ACL repair are young males, a high incidence of urinary retention would be expected.

The possibility arises that the action of morphine administered intra-articularly is via systemic absorption. We have shown in a previous study that the intra-articular administration of morphine results in very low plasma concentrations of morphine and its major metabolites [3]. The plasma concentrations of morphine recorded were less than 10 ng ml^{-1} throughout the sampling period—significantly less than those necessary for systemic analgesia. Systemic absorption effects would not explain the long duration of analgesia achieved after intra-articular injection.

USE OF ALFENTANIL WITH PROPOFOL FOR NASOTRACHEAL INTUBATION WITHOUT NEUROMUSCULAR BLOCK

S. F. E. COGHLAN, P. F. McDONALD AND G. CSEPREGI

SUMMARY

We have investigated the effect of augmentation of propofol with alfentanil for nasotracheal intubation without neuromuscular block in 60 patients undergoing short elective maxillo–facial procedures as outpatients. After administration of glycopyrronium 5 µg kg⁻¹ i.v., anaesthesia was induced with propofol 2.5 mg kg⁻¹, or alfentanil 20 µg kg⁻¹ and profopol 2.5 mg kg⁻¹. The alfentanil group had improved jaw relaxation ($P < 0.001$*) and vocal cord conditions (*$P < 0.005$*). Tracheal intubation was successful in 83% of patients receiving alfentanil, and in 73% of patients receiving propofol only. This difference was not significant. The cardiovascular response to intubation was attenuated in the alfentanil group.* (Br. J. Anaesth. 1993; **70**: 89–91)

KEY WORDS

Anaesthetics, intravenous: propofol. Analgesics: alfentanil. Intubation, nasotracheal: technique.

Patients undergoing short intraoral procedures often require nasotracheal intubation. Suxamethonium has significant side effects in patients rapidly returning to full mobility, while the use of atracurium and vecuronium for short procedures may delay discontinuation of anaesthesia. An induction dose of propofol depresses laryngeal reflexes, enabling laryngoscopy, and abducts and immobilizes the vocal cords. Alfentanil improves conditions for oral intubation using propofol without neuromuscular block [1] and prevents the haemodynamic response to instrumentation. This study was designed to see if augmentation of propofol with alfentanil improves conditions for nasotracheal intubation without neuromuscular block.

METHOD AND RESULTS

We investigated 60 adult patients requiring nasotracheal intubation for elective maxillo–facial surgery as outpatients. All patients were of ASA grade I or II and aged 16–55 yr. Hospital Ethics Committee approval and full written informed consent were obtained.

Patients were allocated randomly to two groups. Premedicant agents were not given. Measurements of mean arterial pressure, heart rate and arterial oxygen saturation were recorded at 1-min intervals from a Criticare 507 monitor. Recordings commenced before any pharmacological agents were given and continued until 3 min after tracheal intubation. Baseline values were taken 3 min after administration of glycopyrronium.

After cannulation of a large forearm vein, glycopyrronium 5 μg kg^{-1} was given and the lungs preoxygenated for 3 min. Group P received propofol 2.5 mg kg^{-1} and group A received propofol 2.5 mg kg^{-1} after administration of alfentanil 20 μg kg^{-1}. Propofol was infused at a rate of 200 mg min^{-1} using an Ohmeda 9000 (BOC) infusion pump. Depth of anaesthesia was assessed 30 s after completion of the infusion by loss of eyelash reflex and a negative response to verbal stimuli. A bolus of propofol 20 mg was given if induction was not complete, or if moving or coughing occurred during instrumentation. Further boluses of propofol were given if necessary. Laryngoscopy was performed in all patients, to see the vocal cords. The total dose of propofol and any response to instrumentation was noted. If intubation was unsuccessful after two attempts, suxamethonium 1 mg kg^{-1} was given.

Quality of intubation was scored according to two criteria: *Jaw relaxation* was classed according to a three-point scale: 1 = full relaxation, laryngoscopy easy; 2 = partial relaxation, laryngoscopy possible; 3 = laryngoscopy not possible.

The *position and movement of the vocal cords* were graded on a four-point scale: 1 = vocal cords abducted, no movement on intubation; 2 = vocal cords abducted but movement during intubation; 3 = vocal cords moving or adducted, intubation possible; 4 = intubation not possible.

Parametric data were analysed using Student's *t* test, paired within groups and unpaired between groups. Jaw relaxation compared class 1 with classes 2 and 3 using a four-fold chi-square test with Yates' correction. The state of the vocal cords was analysed using a two-tailed tie-corrected Mann–Whitney test. Failed intubation rates were compared using the Fisher exact probability test. Events during intubation were compared using "exact' confidence Binomial tables [2].

The two groups were comparable in age, sex and weight; each group comprised 30 patients. Mean dose of propofol to achieve intubation was 3.7 (SD

S. F. E. COGHLAN, M.B., CH.B., DIP.OBST.(OTAGO); P. F. McDONALD, M.B., CH.B., F.R.C.ANAES.; G. CSEPREGI, M.D., D.A.; Department of Anaesthesia, Walton Hospital, Rice Lane, Liverpool L9 1AE. Accepted for Publication: July 25, 1992.

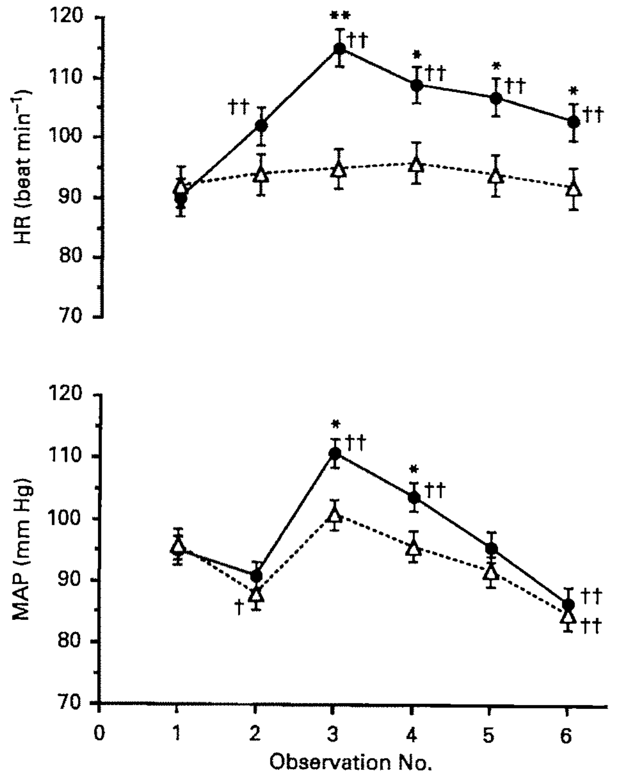

FIG. 1. Mean (SEM) changes in mean arterial pressure (MAP) and heart rate (HR) in patients receiving propofol alone (group P: ●), or with alfentanil (group A: △). Observations: 1 = Baseline; 2 = after induction; 3 = at intubation; 4–6 = 1, 2 and 3 min, respectively, after intubation. Significant differences between groups: $*P < 0.05$; $**P < 0.001$. Significant differences from baseline: $\dagger P < 0.05$; $\dagger\dagger P < 0.01$.

0.5) mg kg^{-1} in group P and 2.9 (0.5) mg kg^{-1} in group A ($P < 0.001$). Mean time to intubation was 157 (89) s in group P and 117 (84) s in group A (ns).

Two patients in group P were in class 1 and 28 in class 2 for jaw relaxation. In group A there were 15 patients in class 1, 13 in class 2 and two in class 3. Jaw relaxation was therefore improved in group A ($P < 0.001$). For vocal cord conditions, in group P there were two patients in grade 1, eight in grade 2, 12 in grade 3 and eight in grade 4. In group A there were 17 in grade 1, five in grade 2, three in grade 3 and five in grade 4. Vocal cord conditions were thus improved in group A ($P < 0.005$).

Intubation was successful in 22 (73%) of the patients in group P and 25 (83%) of the patients in group A (ns). Movement occurred in 28 (93%) of patients in group P and 14 (47%) in group A ($P < 0.01$). Coughing occurred in 29 (97%) of patients in group P and 19 (63%) of those in group A ($P < 0.01$).

In group P, there were significant increases from baseline values in mean arterial pressure and heart rate after intubation. In group A there was a small increase (ns) in mean arterial pressure and no change in heart rate (fig. 1).

COMMENT

We have investigated the potential for nasotracheal intubation without neuromuscular block using propofol either alone, or in combination with alfentanil. The depressant effects of benzodiazepines and topical lignocaine spray were thought to be unsuitable in a group of patients in whom the rapid return of these reflexes is required. All currently available myoneural blockers have undesirable properties when tracheal intubation is necessary for short procedures. Suxamethonium has well-documented side effects, and is tolerated poorly by outpatients. Vecuronium and atracurium, although of shorter duration than other non-depolarizing neuromuscular blockers in clinical use, may delay recovery from anaesthesia after short procedures.

Our results show that conditions for nasotracheal intubation were significantly better when propofol was augmented with alfentanil 20 μg kg^{-1}. Jaw relaxation was improved, vocal cord movement was reduced and the cords abducted. Coughing in response to intubation was decreased significantly, and the pressor response to intubation attenuated.

Keaveney and Knell [3] were successful in 95% of orotracheal intubations using propofol 2.5 mg kg^{-1} alone. Other studies, however, have achieved lower success rates, despite augmentation of propofol with a variety of alternative agents. Lignocaine 1.5 mg kg^{-1} i.v. was ineffective [4] and the combination of fentanyl 1.5 μg kg^{-1} and propofol 2–2.5 mg kg^{-1} provided poor intubating conditions [5].

Alfentanil, with its rapid onset and short duration of action, may be a logical choice of agent for augmenting propofol for short outpatient procedures. It effectively prevents the haemodynamic response to intubation. However, in a study comparing propofol and thiopentone for orotracheal intubation in patients pretreated with lignocaine 1.5 mg kg^{-1} and alfentanil 30 μg kg^{-1}, both groups had poor intubating conditions [6].

Saarnivaara and Klemola [1] assessed various doses of alfentanil in premedicated patients. They achieved an 86% success rate using alfentanil 30 μg kg^{-1} and propofol 2.5 mg kg^{-1}. This is similar to our own rate, despite use of a greater dose of alfentanil, a premedicant agent, and oral rather than nasal intubation.

Guidon-Attali and colleagues have published the only other study of nasotracheal intubation using propofol without neuromuscular block [7]. Patients were premedicated, an induction dose of propofol 3.5 mg kg^{-1} was given, and topical lignocaine spray was applied to the vocal cords and airway. The trachea of all patients was intubated successfully. We feel that the use of topical local anaesthesia is inappropriate when intraoral surgery is performed.

We have found that nasotracheal intubation was achieved readily with a combination of propofol and alfentanil in a group of young, unpremedicated outpatients. More completed intubations could probably have been peformed if more than two attempts at intubation had been made, but the authors felt that this would have compromised the safety of the technique. Other researchers have shown that topical local anaesthetic may further improve intubating conditions but, where this is contraindicated, the combination of propofol 2.5–3.0 mg kg^{-1} and alfentanil 20 μg kg^{-1} provides acceptable conditions for nasotracheal intubation in the majority of patients.

ACKNOWLEDGEMENTS

EFFECT OF ISOMETRIC THUMB PRELOAD ON THE EVOKED COMPOUND MUSCLE ACTION POTENTIAL

I. KALLI

SUMMARY

The effect of thumb preload on adductor pollicis muscle compound action potential (ECAP) was assessed after supramaximal ulnar nerve stimulus during steady isoflurane anaesthesia in 20 ASA I–II patients without neuromuscular block. During thumb preload, the peak-to-peak amplitude of the ECAP increased by 0.9 mV, to 9.5 (SD 2.2) mV ($P < 0.01$), because of the increased height of the negative half-wave. The positive half-wave amplitude did not change, but its duration was prolonged by 0.7 ms, to 6.4 (0.7) ms ($P < 0.05$). Consequently, there was a 15.9% increase in the area of the response curve ($P < 0.01$). Without preload, the first dorsal interosseus muscle peak-to-peak amplitude was 13.0 (4.3) mV. Thus thumb preload may not be the solution to improved monitoring of neuromuscular block by ECAP. (Br. J. Anaesth. 1993; **70**: 92–93)

KEY WORDS

Measurement techniques: neuromuscular junction, electrode position. Neuromuscular transmission: action potentials.

The evoked compound action potential (ECAP) may be recorded on the adductor pollicis muscle in order to monitor neuromuscular block. Electrical ulnar nerve stimulus first evokes an ECAP which is followed by a muscle contraction, but the two responses are different entities. Even so, it has been suggested that ECAP may be altered if constant isometric preload is applied to the muscle [1, 2].

The present investigation was designed to find out if preload applied to the thumb has any clinically notable effect on the ECAP recorded on adductor pollicis muscle.

METHODS AND RESULTS

The study was approved by the Ethics Committee of the Hospital and informed consent was obtained from the patients. We studied 20 healthy ASA I–II female patients (ages 35–50 yr, body weights 50–88 kg) with no disease and receiving no medication affecting the neuromuscular junction. The methods of anaesthesia, standardization of the study and ECAP recordings have been reported previously [3]. Nineteen of the patients had been included in the former study. One patient from that study was excluded because her isometric values were not measured, and she was replaced by another undergoing breast surgery.

The ECAP responses were recorded after a 30-min period of stabilization after induction of anaesthesia, during constant 0.5% (end-tidal) isoflurane and 67% nitrous oxide in oxygen anaesthesia without neuromuscular block. A neuromuscular relaxation monitor (Relaxograph, Datex, Finland) and a memory recorder (Hioki 8810, Hioki, Japan) were used.

The hand was supported in a splint. Initially, the thumb was not fixed and in a neutral position. Two of the disposable surface electrodes (Datex 57268) were positioned on the ulnar nerve. The ECAP was recorded with the active electrode on the motor point of the adductor pollicis muscle and the reference electrode on the second finger. The ground electrode was sited between the stimulus and recording electrodes (fig. 1).

In random order, the adductor pollicis ECAP was recorded without thumb pre-tension and with an isometric preload of 250 g. A calibrated spring dynanometer (155H, Pesola, Switzerland) was used

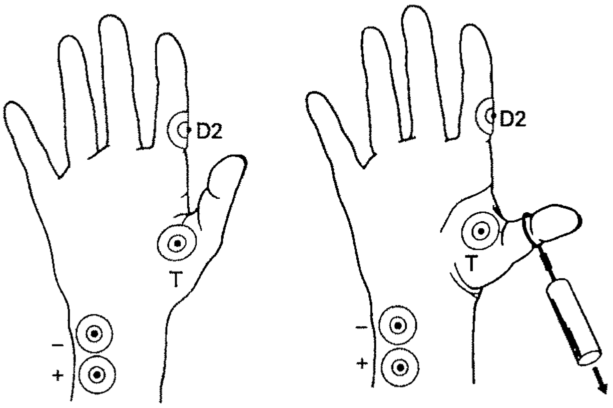

FIG. 1. For evoked compound muscle action potential recordings, the hand was fixed in a splint. Stimulus electrodes were positioned on the ulnar nerve at the wrist (+ and − indicate polarity). The active recording electrode (T) was located on the adductor pollicis muscle motor point. The reference recording electrode (D2) was on the proximal phalanx of the second finger. The ground was between the stimulus and recording electrodes. For the isometric recordings, the thumb was pulled with a constant preload of 250 g (right).

to generate pre-tension, pulling the thumb to the static position opposite the contracting direction of the adductor pollicis muscle.

ECAP characteristics were analysed as described previously [3]. The first of the half-waves which pointed upwards was defined negative. The onset latency, the durations and amplitudes of the negative and positive half-waves, the peak-to-peak amplitude and curve area were measured.

The paired ECAP responses were compared using the Wilcoxon signed rank test. The results were regarded as statistically significant at $P < 0.05$.

A supramaximal response was obtained in all recordings. The finger skin temperature of the recorded hand varied in the range 32.4–34.7 °C.

When the paired ECAP responses were compared, there was no difference between the onset latencies or between the negative half-wave durations. During preload, the mean duration of the positive half-wave was prolonged by 0.7 ms, to 6.4 (0.7) ms ($P < 0.05$). The peak-to-peak amplitude increased to 9.5 (2.2) mV ($P < 0.01$) because of an increase in the height of the negative half-wave by 0.9 mV, to 5.6 (1.4) mV ($P < 0.001$). There was no significant change in the positive half-wave amplitudes.

There was a 15.9% increase ($P < 0.01$) in the total response curve area. The first dorsal interosseus muscle ECAP peak-to-peak amplitude of the 20 patients in the study was 13.0 (4.3) mV.

COMMENT

The ECAP may indeed be amplified slightly by applying preload to the thumb. This change may be a result of the altered recording electrode position in relation to the adductor pollicis muscle [4]. However, the amplitude of that amplified adductor pollicis response was only 73% of the interosseus muscle ECAP amplitude, which was recorded without any preload.

GLYCOPYRRONIUM PROLONGS TOPICAL ANAESTHESIA OF ORAL MUCOSA AND ENHANCES ABSORPTION OF LIGNOCAINE

H. WATANABE, L. LINDGREN, P. ROSENBERG AND T. RANDELL

SUMMARY

We have studied the effect of glycopyrronium on the anaesthetic action and absorption of topical lignocaine in 10 healthy, non-smoking volunteers. Lignocaine 100 mg was sprayed on the oral mucosa 15 min after random administration of glycopyrronium 4 μg kg^{-1} or normal saline i.v. Glycopyrronium decreased the mean analgesia score from 2 to 0.1 (2 = baseline; 0 = anaesthesia) at 4 min compared with a change from 2 to 0.5 after normal saline ($P < 0.05$). All scores returned to baseline by 40 min and 20 min in the glycopyrronium and control groups, respectively. The mean (SD) peak plasma lignocaine concentration was 0.57 (0.29) μg ml^{-1} after glycopyrronium and 0.31 (0.10) μg ml^{-1} after saline ($P < 0.05$) and were attained in 17 min (range 10–40 min) and 29 min (range 8–40 min), respectively. Pretreatment with glycopyrronium enhanced absorption and prolonged the analgesic action of topically administered lignocaine. (Br. J. Anaesth. 1993; **70**: 94–95)

KEY WORDS

Anaesthetic techniques: topical. Anaesthetics, local: lignocaine. Anticholinergics: glycopyrronium.

Topical anaesthetics are often applied to mucous membranes of the airway before laryngoscopy or bronchoscopy [1–3]. The plasma concentrations of lignocaine vary after topical administration [1–4] and absorption is affected by the site and method of administration [3, 5]. It has been suggested that the anaesthetic efficacy and plasma concentrations of a topical local anaesthetic may be affected also by the conditions of the mucous membranes [1, 3, 5].

An anticholinergic agent may be administered before procedures in the mouth and upper airway to inhibit vagal responses and to dry mucous membranes. The present study was designed to evaluate the effect of i.v. glycopyrronium on duration of analgesia and plasma concentrations after topical administration of lignocaine.

METHODS AND RESULTS

After obtaining hospital Ethics Committee approval, we studied 10 healthy, non-smoking volunteers (five females and five males, ages 19–47 yr, weights 55–100 kg) in a randomized fashion. Each subject served as their own control. At least 24 h elapsed between each experiment.

Subjects were studied in the supine position with a 30° head-up tilt. An antecubital vein was cannulated for i.v. administration of drugs and for obtaining blood samples for measurement of plasma concentrations of lignocaine.

After baseline measurements, either glycopyrronium 4 μg kg^{-1} or normal saline was injected in the same volume over 30 s. Before the experiment, the solutions were prepared in coded syringes by a nurse. The i.v. cannula was flushed with 2 ml of normal saline.

The antisialagogue effect was assessed at 1, 2, 3, 5, 10 and 15 min after administration of the solution using a 0–10 visual analogue scale (VAS): 0 = very dry mouth; 10 = very wet mouth. The time elapsed from drug administration to the point when the subject indicated dryness of the mouth was recorded.

Fifteen minutes after drug administration, the subjects inhaled and held their breath, then lignocaine 100 mg (Xylocain, Astra, Sweden) was sprayed over 10 s on the buccal surfaces and the upper part of the soft palate. Subjects were allowed to swallow, but not to spit. Sensation to pinprick in the soft palate was assessed and scored: 0 = no sensation (anaesthesia); 1 = feeling of touch only (analgesia); 2 = normal sensation (baseline). These tests were performed by the same investigator, who was unaware of the dryness score given by the subject.

During the study the ECG was monitored continuously. Heart rate (HR) and arterial pressures (AP) were recorded every 5 min until lignocaine spray. After the spraying, HR and AP were recorded, analgesia tested and blood obtained at 2, 4, 6, 8, 10, 15, 20, 30 and 40 min. Any symptoms of lignocaine toxicity were noted.

Blood samples for measurement of plasma concentrations of lignocaine were obtained in tubes containing dried lithium heparin. After centrifugation, samples were frozen. Lignocaine concentrations

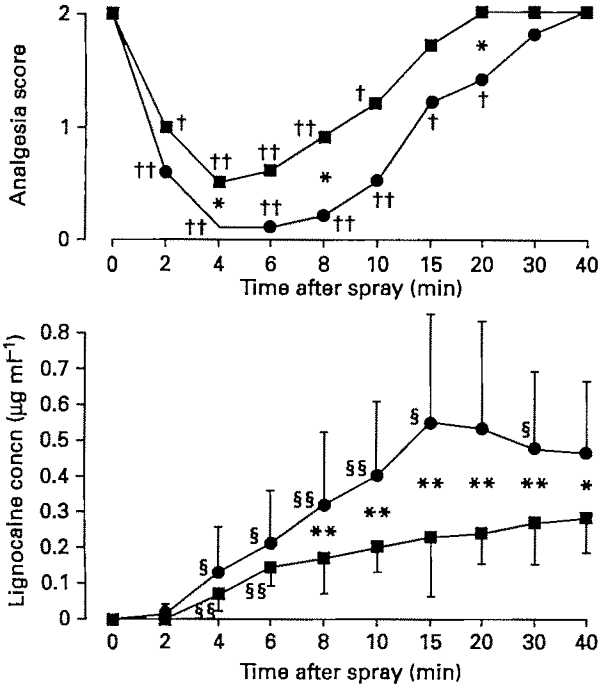

FIG. 1. Analgesia scores (0 = anaesthesia; 1 = analgesia; 2 = baseline) and the plasma concentrations of lignocaine. Time 0 = baseline. ● = Glycopyrronium group; ■ = control group. Significant differences between groups: $^{*}P < 0.05$; $^{**}P < 0.01$. Significant differences within the groups compared with baseline: $\dagger P < 0.05$; $\dagger\dagger P < 0.01$. Significant differences within the groups compared with previous point: $\S P < 0.05$; $\S\S P < 0.01$.

were measured by gas chromatography [6] after completion of the study.

Data were analysed by Wilcoxon signed rank test with $P < 0.05$ considered statistically significant.

After glycopyrronium, the VAS score indicating the degree of dryness of the mouth decreased gradually from mean 6.7 (range 5–10), to 4.3 (2–6) at 15 min ($P < 0.01$). Subjects noted increasing dryness of the mouth 7 min (range 2–15 min) after injection. After saline, the score did not change significantly from baseline (6.9 (5–10)) and none of the subjects reported dryness. During the study, nine of 10 subjects receiving glycopyrronium and six of 10 subjects receiving saline scored sensation to pinprick as 0 (fig. 1).

Mean (SD) peak plasma concentration of lignocaine was 0.57 (0.29) µg ml^{-1} after glycopyrronium and 0.31 (0.10) µg ml^{-1} after saline ($P < 0.05$). The greatest individual lignocaine concentrations were 1.2 µg ml^{-1} and 0.48 µg ml^{-1}, respectively, reached in 17 min (range 10–40 min) and 29 min (range 8–40 min) ($P < 0.05$) (fig. 1). Peak lignocaine concentrations and body weight did not correlate (correlation coefficients: 0.11 in both groups). There were no side effects in any subjects after lignocaine.

Mean (SD) HR increased from 70 (14) beat min^{-1} at baseline to 78 (16) beat min^{-1} at 15 min ($P < 0.05$) and 83 (19) beat min^{-1} 2 min after lignocaine ($P < 0.01$) in subjects receiving glycopyrronium. After saline, HR increased in response to lignocaine, from 68 (10) beat min^{-1} to 76 (19) beat min^{-1} ($P < 0.05$). At 15 min after drug administration, the difference in HR between groups was significant ($P < 0.01$). AP did not change significantly in either group.

COMMENT

It has been suggested that anticholinergic drugs, by drying the mouth, increase the degree of topical anaesthesia [5]. In this study, we found that analgesia scores were on average smaller and the duration of analgesia clearly longer after administration of glycopyrronium.

Absorption of lignocaine through the mucous membranes of the airway is rapid and depends not only on the characteristics of the drug, but also on the site of application, being more rapid from the lower than from the upper airway [5]. Efthimou and colleagues showed that only 5 % of variation in the absorption of lignocaine was attributable to sputum volume or cigarette consumption. The most important factor was the dose per unit body weight [3]. We did not find a positive correlation between the maximal concentration of lignocaine and the dose given, but our results indicate that anticholinergic drugs may enhance topically administered lignocaine absorption. This contradicts results of Morrell, Chappell and White [1]. Their study was not, however, focused on the effect of anticholinergics on lignocaine absorption.

The time to reach peak concentrations after topical lignocaine administration has been found to vary [1–4]. Efthimiou and colleagues sprayed lignocaine on the oral mucosa of unpremedicated volunteers. The dose was larger than ours, but the value of absorption was similar to our control data [3]. Absorption was significantly faster after glycopyrronium in our study. Without anticholinergic pretreatment, topical anaesthetic is diluted and washed by saliva, decreasing contact with the oral mucosa and increasing the amount swallowed. The swallowed lignocaine is probably absorbed slowly in the duodenum, perhaps explaining the slowly increasing and small plasma concentrations.

HAEMODYNAMIC AND METABOLIC CONSEQUENCES OF AORTIC OCCLUSION DURING ABDOMINAL AORTIC SURGERY

D. G. WHALLEY, F. C. SALEVSKY AND J. V. RYCKMAN

SUMMARY

We have studied the haemodynamic and metabolic effects of application and removal of the infrarenal aortic crossclamp in 20 patients during aortic reconstructive surgery for repair of aneurysmal or occlusive disease. A highly significant positive correlation was detected between the change in systemic vascular resistance (SVR) associated with application of the aortic crossclamp and the change in base deficit (BD) associated with its removal ($r = 0.851$; $P = 0.001$). There was no difference in regression analysis ($P = 0.21$) or mean change of SVR and BD ($P = 0.73$) in patients with either aneurysmal or occlusive disease. In addition, the maximum increase in mixed venous serum lactate concentration correlated positively with the duration that the aortic crossclamp was applied ($r = 0.717$, $P = 0.0297$). These observations suggest the importance of the collateral circulation in the development of metabolic acidosis during aortic surgery. (Br. J. Anaesth. 1993; **70**: 96–98).

KEY WORDS

Acid–base equilibrium: base deficit. Arterial pressure: systemic vascular resistance. Surgery: aortic.

Application of an infrarenal aortic crossclamp during aortic reconstructive surgery may be associated with substantial increases in systemic vascular resistance and arterial pressure which, in patients with coronary artery disease, may further compromise cardiac performance by increasing myocardial wall tension [1]. There is evidence that patients undergoing aortic reconstructive surgery for occlusive disease experience smaller increases in systemic vascular resistance at the time the crossclamp is applied than those patients with aneurysmal disease, presumably because of better developed collateral vascularization in the former [2], but these data conflict with the experience of other workers who have found no such distinction [3]. Cunningham and colleagues were unable to demonstrate differences in the immediate haemodynamic consequences of crossclamping the aorta between patients with occlusive or aneurysmal disease, but noted that the extent of collateral circulatory changes associated with occlusive disease influenced the magnitude of haemodynamic changes during the period the aorta was crossclamped [3].

Studies of the metabolic effects of aortic reconstructive surgery have demonstrated increases in Pa_{CO_2} and venous serum lactate concentrations after release of the aortic crossclamp, but no consistent change in pH [4, 5]. The increase in serum lactate concentration begins during the time the aorta is crossclamped and persists into the immediate postoperative period, suggesting that the metabolic consequences of peripheral ischaemia begin at the time of application of the aortic crossclamp or shortly thereafter [4].

The hypothesis of the present study was that the immediate haemodynamic changes associated with application of the aortic crossclamp during aortic reconstructive surgery reflect the degree of collateral vascularization [2, 3] and therefore the degree of peripheral ischaemia, irrespective of whether the patient has occlusive or aneuysmal disease, and that the magnitude of such changes predicts the subsequent metabolic disturbances that occur after removal of the crossclamp. We have therefore examined the relationship between haemodynamic and metabolic changes during aortic surgery.

METHODS AND RESULTS

In a prospective study approved by the local Ethics Committee, we have made observations in 20 patients (17 male) undergoing infrarenal aortic reconstructive surgery. The aorta was aneurysmal in 12 patients and in the remaining eight patients surgery was undertaken for correction of atherosclerotic occlusive disease. Mean age of the patients was 70.3 yr and mean (SD) height, weight and BSA were 174.7 (9) cm, 76.4 (15.3) kg and 1.88 (0.26) m^2, respectively. Patients received their usual cardiovascular medication before surgery, and premedication with either diazepam 5 mg orally or midazolam 1–2 mg i.v. Before induction of anaesthesia, i.v., i.a. and thermodilution pulmonary artery catheters were inserted under local anaesthesia and control haemodynamic variables measured. These included heart rate, mean arterial pressure (MAP), systemic vascular resistance (SVR), cardiac output (CO), central venous pressure and pulmonary capillary wedge pressure (PCWP).

Anaesthesia was induced with fentanyl 10 $\mu g\ kg^{-1}$ and a sleep dose of thiopentone followed by pan-

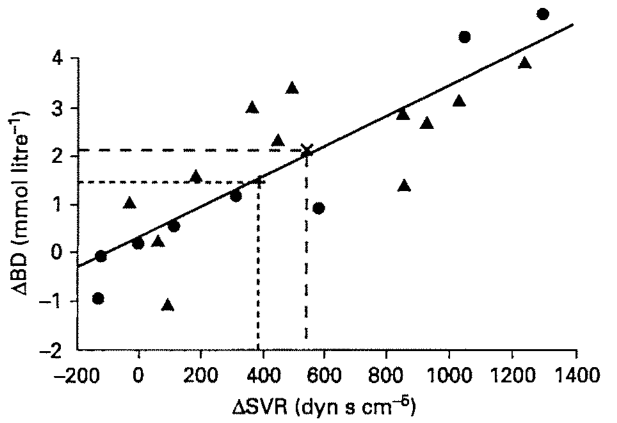

FIG. 1. Relationship between change in SVR from before to after application of the aortic crossclamp (ΔSVR) and change in base deficit from before to after release of the aortic crossclamp (ΔBD) in patients with aneurysmal disease (▲) or occlusive disease (●). —x— = Mean ΔSVR and mean ΔBD for patients with aneurysmal disease; ---+--- = mean ΔSVR and mean ΔBD for patients with occlusive disease. $r = 0.851$; $P = 0.0001$.

curonium 0.1 mg kg^{-1} to facilitate tracheal intubation. Anaesthesia was maintained with nitrous oxide in oxygen, enflurane to an end-tidal concentration of 0.5–1.5 % and periodic administration of pancuronium 1 mg to prolong neuromuscular block. Ventilation was adjusted to $P\text{E}'_{CO_2}$ 3.32–3.99 kPa immediately after induction and was not altered during surgery.

Ringer's lactate and packed red cells were given i.v. to maintain the PCWP at pre-induction values and the PCV > 25 %.

Patients' lungs were ventilated during the immediate postoperative period until the pulmonary artery temperature was > 36 °C, whereupon they were considered suitable for tracheal extubation.

Additional haemodynamic variables were obtained periodically during surgery, but specifically, immediately before and within 5 min after application of the aortic crossclamp and immediately before and 15 min after removal of the aortic crossclamp. Mixed venous and arterial blood-gas analysis, mixed venous serum lactate concentrations and end-tidal carbon dioxide measurements were obtained before induction of anaesthesia, before and after application of the aortic crossclamp, before and after removal of the aortic crossclamp and at 5 min, 10 min and 15 min after unclamping.

Using linear regression analysis, the maximum changes in mixed venous serum lactate concentrations, mixed venous $P\text{CO}_2$ and extracellular fluid base deficit were correlated with the duration that the aorta was crossclamped (range 20–92 min) and the change in MAP, SVR and CO associated with application of the aortic crossclamp. The base deficit (BD) was derived from the standard bicarbonate (HCO_3) and pH ($BD = 24 - HCO_3 + 12\ [7.4 - pH]$) and the correlations were considered significant at $P < 0.05$ [6].

A highly significant positive correlation was demonstrated between the base deficit revealed after the crossclamp was removed and the increase in SVR associated with application of the crossclamp ($r = 0.851$, $P = 0.0001$; $\Delta BD = 0.36 + 0.003\ [\Delta SVR]$) (fig. 1). There was a trend to a significant relationship between the changes in venous serum lactate and SVR ($P = 0.09$), but there was a significant difference between the change in venous serum lactate concentration and the duration of aortic crossclamp ($r = 0.717$, $P = 0.0297$; $\Delta\text{lactate} = -0.64 + 0.038$ [duration of aortic crossclamp]). No other correlation was significant.

The data were analysed further to determine if the significant relationship between ΔBD and ΔSVR differed for those patients with aneurysmal or occlusive disease. Regression lines were constructed for both groups, but analysis of covariance showed no interaction ($P = 0.16$) and no difference ($P = 0.21$). Furthermore, subsequent analysis using the Hotelling's T^2 test for simultaneous comparison of continuous, dependent data revealed no difference between the groups in the mean ΔBD and mean ΔSVR (mean (SD): aneurysm group ΔBD 2.11 (1.4) mmol litre^{-1}, ΔSVR 539.25 (427.7) dyn s cm^{-5}; occlusive group ΔBD 1.45 (2.1) mmol litre^{-1}, ΔSVR 379.9 (541.7) dyn s cm^{-5}) ($P = 0.73$), suggesting that under the conditions of the study the two groups were from the same patient population.

COMMENT

We have demonstrated a significant relationship between the haemodynamic effects expressed as a change in SVR associated with the application of the aortic crossclamp and the subsequent metabolic acidosis expressed as an increase in base deficit revealed after the crossclamp was removed. Furthermore, the increase in mixed venous serum lactate concentrations was related directly to the duration of aortic crossclamp. These observations suggest that it is the patency of the collateral circulation as reflected in the haemodynamic changes at the time of crossclamp that governs the degree of anaerobic metabolism suffered by the partially ischaemic tissues during the time the aorta is occluded, and the subsequent metabolic acidosis revealed upon reperfusion.

We have measured the blood-gas tensions and serum lactate concentrations in mixed venous blood to determine more accurately the acid–base status of the tissues and we have confirmed the metabolic changes during aortic reconstructive surgery described by others [4, 5]. $P\bar{v}_{CO_2}$ and pH consistently increased and decreased, respectively, upon release of the crossclamp, but the magnitude of the changes was too variable to correlate significantly with the haemodynamic changes.

The mixed venous serum lactate concentration began to increase shortly after application of the aortic crossclamp and the increase continued while the crossclamp was in place. This observation is in agreement with that of Anderrson and colleagues, who, in addition, described further increases in venous serum lactate concentration 60 min after removal of the crossclamp [4]. However, the increases in the present study did not correlate with haemodynamic changes, suggesting that serum lactate concentration is a more sensitive indicator of the adequacy of oxygen delivery than alteration in SVR.

In contrast with Johnson and colleagues [2], we were unable to distinguish between the haemodynamic changes associated with application of the aortic crossclamp in patients with aneurysmal disease and those with occlusive disease. There was no difference in the mean change in SVR between the two groups of patients at the time of aortic crossclamp, suggesting a similar degree of collateral circulation in each group and an overlap of the disease process. Furthermore the relationship between ΔSVR and ΔBD was similar for both groups. Although the sample size was small, the regression lines for each group showed significant correlation, but no interaction and no statistical difference between them.

PROPOFOL DECREASES RANDOM AND CHEMOTACTIC STIMULATED LOCOMOTION OF HUMAN NEUTROPHILS *IN VITRO*

A. G. JENSEN, C. DAHLGREN AND C. EINTREI

SUMMARY

We have studied the influence of clinical concentrations of propofol (2,6-diisopropyl phenol), emulsified propofol (Diprivan) and the emulsifier of propofol (Intralipid 10%) on random and chemotactic locomotion of human polymorphonuclear leucocytes in an agarose assay. Random locomotion was decreased ($P < 0.001$) to a similar extent by the three drugs. Concentrations of propofol 2.5 μg ml^{-1} and greater, and of Diprivan 3.33 μg ml^{-1} and greater, also reduced chemotaxis ($P < 0.05$) against both zymosan-activated human serum (C5a) and N-formyl-methionyl-leucyl-phenylalanine (FMLP), used as chemoattractants. Intralipid reduced chemotaxis towards C5a but not towards FMLP. We conclude that propofol in clinically relevant concentrations may adversely affect leucocyte locomotion in vitro. (Br. J. Anaesth. 1993; **70**: 99–100)

KEY WORDS

Anaesthetics, intravenous: propofol. Blood: leucocytes. Toxicity: leucocyte chemotaxis.

Anaesthetics may compromise host defence mechanisms by adversely affecting the specific or non-specific components of the normal immune response. The migration of neutrophils is one of the earliest events in the body's non-specific defence against infection. Adverse effects of general anaesthetic agents on neutrophil function *in vitro* are important as, theoretically, they could imply compromised function *in vivo*; a depressed immune response after anaesthesia may lead to an increased incidence of postoperative infections.

We have investigated the effect of propofol on the random and chemotactic locomotion of human polymorphonuclear neutrophils. Propofol, in the clinically used preparation 10 mg ml^{-1}, is dissolved in a fat emulsion with a composition identical to that of Intralipid 100 mg ml^{-1} (Kabi Vitrum, Stockholm, Sweden). It is known that Intralipid depresses both random and directed locomotion of neutrophilic granulocytes [1]. To study the effect of both the emulsifier and the active drug, we investigated the effects of Diprivan and used both pure propofol and Intralipid as controls.

METHODS AND RESULTS

Venous blood was obtained from 15 healthy adult volunteers and neutrophils were separated from heparinized blood using standard techniques [2]. Agarose (Litex, Copenhagen, Denmark) was dissolved in 60 ml of water by heating (1.2% w/v). After temperature equilibration, equal volumes of the agarose solution and of double-concentrated Geys medium and 2% human serum albumin were mixed. This solution was supplemented and mixed with the drug under investigation and poured into tissue culture dishes (60 × 13 mm; Flow, Edinburgh, Scotland). Twelve holes were cut in the agarose using a specially constructed mould. After addition of 10 μl of normal human serum containing zymosan (C5a) 5 mg ml^{-1} to two of the holes in each plate, the plates were incubated for 1 h at 37 °C in 5% carbon dioxide. Ten microlitre of the cells was added to the six holes in the centre of the plate and 10 μl of N-formyl-methionyl-leucyl-phenylalanine (FMLP) 10^{-7} mol litre^{-1} was added to two of the holes at the periphery. The plates were then incubated for 60 min under the same conditions as before. The cells were fixed in 3.7% cold formalin, and stained with Giemsa.

The migration distance was measured under a microscope, measuring on an arbitrary scale the distance from the edge of the well to the leading front of neutrophils [3]. The mean and SD of at least 12 readings were calculated for each concentration and drug. The significance of the difference in migration in arbitrary scale units between the control cells and the cells treated with different drugs and different concentrations was assessed by Student's t test. $P < 0.05$ was considered significant.

The effects on granulocyte locomotion of four different concentrations of Diprivan were studied: 1.66 μg ml^{-1}, 2.5 μg ml^{-1}, 3.33 μg ml^{-1} and 33.3 μg ml^{-1}. Random locomotion was reduced significantly by Diprivan—by about 50% for all the concentrations used. Directional locomotion towards

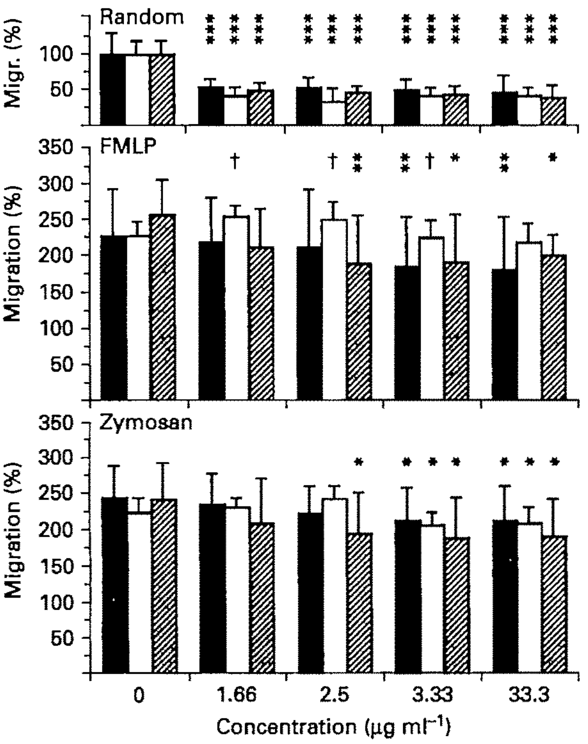

FIG. 1. Mean (SD) locomotion of leucocytes at random and after stimulation with FMLP and zymosan (C5a), at different concentrations of Diprivan (■) propofol (▨) and Intralipid (☐) (concentrations of Intralipid 10 times greater than noted). 100% migration = distance of random migration in controls without drug. Significant differences: $*P < 0.05$, $**P < 0.01$ and $***P < 0.001$—compared with respective migration at concentration 0; $\dagger P < 0.05$—Intralipid compared with Diprivan and propofol.

FMLP and C5a was reduced to a similar degree with Diprivan 3.33 µg ml^{-1} and 33.3 µg ml^{-1}. Reduction of random locomotion was more pronounced than the reduction observed after chemoattractants (fig. 1).

The results using propofol were similar to those with Diprivan, as random locomotion was reduced by all the concentrations investigated. Directed locomotion in response to both FMLP and C5a was significantly reduced with concentrations of propofol 2.5 µg ml^{-1} and greater (fig. 1).

The Intralipid concentrations used during this study were 16.6 µg ml^{-1}, 25 µg ml^{-1}, 33.3 µg ml^{-1} and 333.3 µg ml^{-1}. Random locomotion was reduced also with Intralipid. The degree of reduction was similar to that with Diprivan and propofol. However, Intralipid did not reduce the migration when FMLP was used as chemoattractant (fig. 1). Directional locomotion towards C5a was reduced with Intralipid in concentrations greater than 33.3 µg ml^{-1}, to a similar degree as that with Diprivan (fig. 1).

COMMENT

The major findings of this study were that clinically relevant concentrations of Diprivan depressed migration of the human neutrophil granulocyte. As the reduction was comparable with Diprivan, propofol and Intralipid for random migration and directed migration towards C5a, we conclude that both the drug propofol *per se* and the emulsifier with a composition similar to that of Intralipid were responsible for the influence on the granulocytes. These effects were neither additive nor concentration-dependent. The depressed migration ability of granulocytes after Intralipid incubation in our study was comparable to the results obtained in a previous study [1] in which an *E. coli* culture filtrate was used as chemotactic agent. With the design of our study we were not able to determine whether or not the impairment was reversible after discontinuation of the anaesthetic, and the clinical significance of this inhibition has not yet been determined. However, any impairment of the responsiveness of the leucocyte is likely to increase the incidence of infection. The Leucocyte Adhesion Deficiency, in which defects in neutrophil chemotaxis and phagocytosis lead to widespread bacterial infections, is an example of such an impairment [4].

Leucocytes have been shown to engulf Intralipid, resulting in reduction in important cell membrane constituents and impaired locomotion [1]. The mechanism by which propofol interferes with the locomotor process is not known but, as propofol is lipid soluble, the depressing effect of this agent on random locomotion could also be mediated by membrane changes induced by the drug. Also, the compounds used in this study could possibly exert their effect on migration by disruption of the contractile system.

Specific receptors for C5a and for FMLP on the surface of neutrophils have been demonstrated, and their recycling patterns are different, as are the basic mechanisms for recognition of chemotactic gradients [5]. This could possibly explain the different results found using these two chemoattractants. The turnover of receptors, and the ability to detect a surface bound gradient, may be disturbed by lipid soluble molecules that can be inserted into lipid membranes. The degree of depression of chemotactic locomotion observed with inhalation anaesthetic agents parallels their lipid solubilities [6] and we suggest that propofol could depress locomotion of leucocytes by the same mechanisms as the inhalation anaesthetics.

ACKNOWLEDGEMENT

The authors thank ICI for supplying propofol.

CASE REPORTS

USE OF TRANSOESOPHAGEAL ECHOCARDIOGRAPHY TO MANAGE BETA-ADRENOCEPTOR BLOCK AND ASSESS LEFT VENTRICULAR FUNCTION IN A PATIENT WITH PHAEOCHROMOCYTOMA

T. RYAN, A. TIMONEY AND A. J. CUNNINGHAM

SUMMARY

A case of phaeochromocytoma is reported in which perioperative hypertension was controlled with an infusion of esmolol. Transoesophageal echocardiography was used in addition to conventional monitoring to manage i.v. fluid administration and assess perioperative changes in left ventricular function. (Br. J. Anaesth. 1993; **70**: 101–103)

KEY WORDS

Monitoring: echocardiography. Pharmacology: esmolol. Surgery: phaeochromocytoma.

Phaeochromocytoma is a catecholamine-secreting tumour which arises usually from the adrenal medulla. This rare tumour may be associated with significant perioperative morbidity and mortality [1, 2]. Esmolol, an ultra-short-acting beta-adrenoceptor blocking agent, may be used to control intraoperative hypertension and tachycardia. This report describes a case in which transoesophageal echocardiography was used to assist intraoperative fluid management and to assess left ventricular function when esmolol infusion was administered during resection of a phaeochromocytoma.

CASE REPORT

A 25-yr-old, 50-kg female presented with an 8-month history of hypertension and tachyarrhythmias. The 24-h urinary concentrations of noradrenaline 1630 µg (normal < 100 µg) and adrenaline 54 µg (normal < 20 µg) were increased. Computed axial tomography demonstrated bilateral adrenal masses consistent with a diagnosis of phaeochromocytoma. Preoperative preparation included alpha-adrenoceptor block with phenoxybenzamine 20 mg orally 8-hourly and propranolol 10 mg orally 6-hourly for 10 days before surgery. There was no evidence of cardiac failure on physical examination or chest radiography. Electrocardiography revealed left ventricular hypertrophy without ST- or T-wave abnormalities. Ambulatory arterial pressure monitoring for 24 h before surgery revealed systolic pressures in the range 100–180 mm Hg and diastolic pressures of 60–90 mm Hg.

Diazepam 10 mg was administered orally 60 min before surgery. Monitoring before induction of anaesthesia consisted of an ECG in the cm5 configuration, direct measurement of arterial pressure and pulse oximetry. Anaesthesia was induced with fentanyl 400 µg and thiopentone 250 mg, followed by vecuronium 10 mg. The lungs were ventilated by mask with 2% isoflurane in oxygen until muscle relaxation was adequate to permit attempts at laryngoscopy and tracheal intubation. Esmolol 0.5 mg kg^{-1} and lignocaine 1.5 mg kg^{-1} were administered to attenuate adverse haemodynamic responses to laryngoscopy and intubation. Anaesthesia was maintained with 0.5–1.0% isoflurane and 50% nitrous oxide in oxygen. A thermodilution pulmonary artery catheter was inserted via the right internal jugular vein and a 5-MHz transoesophageal echocardiac probe (Hewlett–Packard 77020) was inserted to view the short axis of the left ventricle at mid papillary muscle level. This view allows left ventricular cross sectional area to be measured at end-systole (LVESA) and end-diastole (LVEDA) by the following method. Transgastric images of the left ventricular short axis at mid papillary muscle level, gated by an ECG, are recorded on video tape. On replay of individual frames, the left ventricular cavity may be outlined by a light pen. Software incorporated in the ultrasound machine measures the areas outlined. LVEDA is defined as that area which coincides with the peak of the R wave of an ECG; LVESA is taken as the smallest left ventricular cross sectional area. Measurements from three consecutive sinus beats were averaged to arrive at each value of LVEDA and LVESA. Area ejection fraction (AEF) may be derived from LVEDA and LVESA:

$$\text{AEF} = (\text{LVEDA} - \text{LVESA})/\text{LVEDA}$$

Baseline measurements of cardiac index (CI), pulmonary artery occlusion pressure (PAOP), arterial pressure (AP), LVESA, LVEDA and AEF were recorded after tracheal intubation and before surgical incision. M-mode echocardiac measurement of end-diastolic left ventricular free wall thickness, at 1.9 cm, was diagnostic of left ventricular hypertro-

phy. Two-dimensional echocardiography demonstrated a small but vigorously contracting left ventricle.

Colloid solution 1.5 litre was infused rapidly. This was associated with an increase in PAOP from 7 to 12 mm Hg and LVEDA from 9.1 to 13.6 cm^2. Simultaneous increases in AEF (from 48 to 51%) and stroke volume (from 85 to 120 ml) were recorded. Table I details the haemodynamic and echocardiographic data collected during the surgical procedure. An infusion of esmolol 0.1 mg kg^{-1} was commenced in response to hypertension at skin incision, resulting in an increase in LVESA with reduced AEF and stroke volume (table I). Esmolol infusion reduced AEF to a minimum of 30%, with an associated maximum LVESA of 9.7 cm^2. LVEDA was used to assess requirement for i.v. fluid administration. An additional 2 litre of crystalloid solution was necessary to maintain LVEDA in the range 13–16 cm^2. Simultaneous measurements of PAOP at each assessment of LVEDA (table I) varied from 12 to 21 mm Hg. Catecholamine release at tumour manipulation (table I) caused transient hypertension and increase in heart rate, with little change in stroke volume or ejection fraction. Arterial pressure was unchanged after ligation of the venous drainage of the tumour. At termination of surgery, when esmolol infusion was discontinued, LVESA decreased, with associated increase in arterial pressure, AEF and cardiac index (table I). As the estimated intraoperative blood loss was 500 ml, homologous blood was not transfused. The patient's postoperative recovery was uneventful. Histology confirmed the presence of bilateral phaeochromocytoma.

DISCUSSION

The traditional management of hypertension and tachycardia associated with phaeochromocytoma excision combines preoperative preparation with alpha-adrenoceptor block and intraoperative use of potent vasodilators such as nitroprusside [1]. Hypertensive episodes caused by surges in plasma catecholamine concentrations may be observed at tracheal intubation, skin incision and tumour manipulation. Hypotension may occur after ligation of the venous drainage of the tumour and is mainly a result of hypovolaemia [2].

Two-dimensional echocardiography may be used to assess left ventricular function by calculating area ejection fraction from end-diastolic and end-systolic left ventricular areas. Transoesophageal echocardiography (TE) may be used to provide a reliable and reproducible index of peroperative left ventricular end-diastolic volume and ejection fraction. Abel and colleagues found the median intra-observer variability in measurement of AEF to be 3%, with a 75th percentile of 5.75% [3]. Smith and colleagues showed that deliberate repositioning of a TE probe does not result in significant change in measured values of LVEDA and LVESA [4]. Additionally, LVEDA and AEF on TE correlate significantly with radionuclide measurement of end-diastolic volume and ejection fraction [5].

Ejection fraction is dependent on both preload and afterload and thus is an imprecise index of left ventricular function. However, LVESA is related linearly to systemic arterial pressure [6]. With constant arterial pressure, deteriorating contractility should be accompanied by increased LVESA on TE. This relationship between systemic arterial pressure and LVESA may be used to assess contractility. In a report on echocardiographic findings associated with phaeochromocytoma, Shub and colleagues [7] documented normal systolic function in 23 of 26 patients. In this patient, before surgical incision and esmolol infusion, TE left ventricular short axis imaging demonstrated normal systolic function. Esmolol reduces left ventricular contractility and the infusion of esmolol induced a marked reduction in ejection fraction during surgery. This was reversed temporarily, on tumour manipulation, presumably because of an increase in catecholamine concentrations. LVESA was increased by infusion of esmolol, despite near constant systemic arterial pressure. LVESA and AEF returned to baseline values shortly after esmolol was discontinued. These echocardiographic measurements, AEF and LVESA, served as an index of myocardial function against which esmolol infusion may be titrated.

Pulmonary artery occlusion pressure represents an estimate of left ventricular end-diastolic pressure and, in comparison with TE-derived LVEDA, is an imprecise index of left ventricular end-diastolic volume [5]. In the presence of impaired left ventricular compliance, secondary to left ventricular hypertrophy, hypovolaemia may occur when PAOP lies within the normal range. Intraoperative M-mode TE was used in our patient to confirm a preoperative diagnosis of left ventricular hypertrophy. Left ventricular free wall thickness was 1.9 cm, compared with normal limits of 1–1.2 cm [8]. Hypovolaemia is an important contributing factor to the profound hypotension that may occur after removal of a phaeochromocytoma [1]. In this patient, TE two-dimensional echocardiographic measurement of LVEDA was used to monitor left ventricular preload. I.v. fluids were titrated to maintain LVEDA on TE at the value attained after initial infusion of i.v. fluids. PAOP varied from 12 to 21 mm Hg during surgery, despite minimal changes in LVEDA on TE (13.6–15.9 cm^2). In this manner, occult hypovolaemia was avoided and hypotension after tumour removal was prevented.

Although preoperative medication with alpha-adrenoceptor blocking drugs remains a cornerstone of management, the role of newer beta-adrenoceptor blockers such as esmolol has not been fully evaluated. The use of beta-adrenergic block has been limited by two major concerns. First, in the presence of a catecholamine-induced cardiomyopathy, these negative inotropic agents might precipitate cardiac failure. Second, peripheral beta-adrenoceptor block may oppose peripheral vasodilatation and augment pre-existing hypertension [1, 2]. Esmolol is a short-acting beta-adrenoceptor blocker which acts within 2 min and has an elimination half-life of 9 min [9]. Thus myocardial dysfunction produced by esmolol is of short duration. As esmolol is also highly cardioselective, it has no peripheral actions [10]. Beta-adrenoceptor block may also be beneficial in preventing perioperative tachyarrhythmias. Esmolol has been used safely as part of the intraoperative management of phaeochromocytoma without either precipitating cardiac failure or aggravating hypertension [11,12]. Thus esmolol should be considered in the prevention and control of hypertension at resection of a phaeochromocytoma when left ventricular systolic function is normal. However, the considerable cost of an esmolol infusion represents a potential disadvantage of this approach.

Vasodilators were not used in the peroperative control of arterial pressure in this patient. Preoperative electrocardiographic evidence of left ventricular hypertrophy was confirmed by intraoperative M-mode echocardiography. Diastolic dysfunction with impaired left ventricular compliance is a consequence of hypertension-induced left ventricular hypertrophy [13]. In the presence of left ventricular hypertrophy, LVEDP should be maintained sufficient to ensure adequate stroke volume and cardiac output. Brush and colleagues [14] utilized nuclear ventriculography and intraventricular pressure monitoring to compare the effects of nitroprusside and verapamil on left ventricular function in hypertensive patients. Nitroprusside, a potent vasodilator, reduced left ventricular end-diastolic pressure. Thus left ventricular end-diastolic volume and cardiac output were reduced by infusion of nitroprusside. In contrast, although verapamil reduced left ventricular contractility, it maintained stroke volume and cardiac output. Brush's group concluded that it is more appropriate to control systemic hypertension with a negative inotropic agent when left ventricular compliance is reduced and ventricular systolic function is normal. Indeed, Topol, Traill and Fortuin [15] suggested that negative inotropic agents are the hypotensive agents of choice in patients with left ventricular hypertrophy. In the patient reported here, phaeochromocytoma was associated with left ventricular hypertrophy and preserved left ventricular systolic function. Vasodilating hypotensive agents may be contraindicated in this patient.

SUMMARY

In patients suffering from hypertrophic obstructive cardiomyopathy (HOCM), any catecholamine release during anaesthesia may aggravate the severity of the outflow tract obstruction and compromise cardiac output. In this event the situation may be improved by beta block. Esmolol, an ultra-short-acting beta-blocker (half-life 9 min) appears to be a suitable agent for this purpose. We describe its use in the perioperative management of a patient who underwent surgical correction of HOCM. (Br. J. Anaesth. 1993; **70**: 104–106)

KEY WORDS

Complications: hypertrophic obstructive cardiomyopathy. Sympathetic nervous system: β-adrenoceptor block, esmolol.

Hypertrophic obstructive cardiomyopathy (HOCM) is transmitted genetically as an autosomal dominant with a high degree of penetrance [1–3]. The anatomical abnormality is asymmetrical hypertrophy of the interventricular septum, with bizarrely shaped and disorganized cardiac muscle fibres. This is believed to be caused by an increased density of voltage-sensitive calcium channels which impair normal muscular relaxation [2]. The result is an outflow tract obstruction between the left ventricle and the aortic valve, with accompanying left ventricular hypertrophy and poor left ventricular compliance. The obstruction is made worse during systole by exaggerated movement of the anterior mitral valve leaflet towards the septum, the so-called systolic anterior motion (SAM) [3]. Clinical manifestations of the disease include angina, dyspnoea, palpitations and syncope. There is also an increased incidence of sudden death attributable to ventricular arrhythmias.

Surgical correction of HOCM, by either septal myotomy or partial myomectomy, is usually reserved for patients with severe symptoms despite optimal drug therapy or with evidence of a large outflow tract gradient [4]. The main anaesthetic consideration is to prevent or minimize any factor that would increase the outflow tract gradient perioperatively. We present the case report of a patient who underwent surgical correction of HOCM. During the immediate post-cardiopulmonary bypass period and after operation, in the intensive care unit, we used esmolol, with improvement in the outflow tract gradient.

CASE REPORT

A 54-yr-old lady presented to the cardiology clinic with a 6-month history of increasing central chest pain on exertion. She had no previous medical history. On examination, she had a resting arterial pressure of 130/80 and her heart rate was 72 beat min^{-1}, regular. An early systolic murmur was detected at the apex, radiating into the aortic area. Her exercise test was positive, with ST segment changes greater than 2 mm in leads V5 and V6. An echocardiogram was performed which showed a hypertrophied left ventricle. Subsequent cardiac catheterization revealed a gradient of 84 mm Hg between the left ventricle and the outflow tract, and a gradient of 21 mm Hg between the outflow tract and the aorta. The coronary arteries were normal and the patient was scheduled to undergo myomectomy of the left ventricular outflow tract 2 weeks later.

On the day of the operation, she was premedicated with diazepam 10 mg 2 h before operation and papaveretum 15 mg and hyoscine 0.3 mg 1 h before operation. Before induction, a peripheral i.v. cannula was inserted and direct arterial pressure monitoring commenced via a 20-gauge cannula in the left radial artery. Anaesthesia was induced with fentanyl 250 μg, thiopentone 150 mg and pancuronium 12 mg. After tracheal intubation, intermittent positive pressure ventilation was commenced and anaesthesia maintained with nitrous oxide and enflurane in oxygen, and incremental doses of fentanyl as clinically indicated. A central venous cannula and a pulmonary artery thermodilution catheter were inserted via the right internal jugular vein.

Baseline haemodynamic readings before surgical incision are shown in table I. Sternotomy produced an increase in arterial pressure to 150/90 mm Hg which was controlled by a further incremental dose of fentanyl 250 μg. Thereafter, all the cardiovascular parameters remained stable until cardiopulmonary bypass (CPB) was commenced.

During CPB, the patient was cooled to 28 °C, the aorta was crossclamped and cardioplegia solution 700 ml infused. The aortic valve was exposed and

TABLE I. *Haemodynamic data before and after cardiopulmonary bypass*

	Heart rate (beat min^{-1})	AP (mm Hg)	CVP (mm Hg)	PCWP (mm Hg)	LV outflow tract gradient (mm Hg)
Immediately before CPB	80	130/80	6	9	84
Immediately after CPB	100	80/60	6	10	50
15 min after esmolol	75	130/80	8	13	10
15 min after end esmolol	85	100/60	8	12	25
15 min after esmolol restart	80	125/70	8	12	10

found to be normal, and hypertrophic muscle was seen in the outflow tract through the aortic valve. Myomectomy was performed on the left ventricular outflow tract. Immediately after discontinuation of CPB, arterial pressure was 80/60 mm Hg. The filling pressure was increased to a PCWP of 12 mm Hg with colloid and trial use of the vasoconstrictor metaraminol failed to produce any improvement in arterial pressure. Measurement of the pressures within the left ventricle and the left ventricular outflow tract revealed a gradient of 50 mm Hg. CPB was recommenced and esmolol 3 mg kg^{-1} h^{-1} infused after a loading dose of 500 μg kg^{-1} given over 1 min. Fifteen minutes later, CPB was again discontinued. Cardiovascular variables improved significantly and the left ventricular outflow tract gradient was now 10 mm Hg. The patient remained haemodynamically stable for 30 min, whereupon the esmolol was discontinued. Within 15 min, however, the left ventricular outflow tract gradient had increased to 25 mm Hg. The esmolol infusion was recommenced and the haemodynamic state improved.

The patient remained haemodynamically stable thereafter and after completion of surgery she was transferred to the intensive care unit. The esmolol infusion was continued for another 12 h at a rate of 2 mg kg^{-1} h^{-1}; filling pressures were maintained at optimal values and she remained stable. The following morning the trachea was extubated and the esmolol infusion was discontinued when oral propanolol had been instituted.

DISCUSSION

One of the features of HOCM is the dynamic nature of the outflow tract obstruction. The degree and timing of SAM-septal contact of the anterior mitral valve leaflet determines the dynamic pressure gradient [3] and it is influenced by myocardial contractility, preload and afterload. Hypovolaemia, peripheral vasodilatation and increased sympathetic tone increase the pressure gradient while, paradoxically, factors which usually impair left ventricular performance, such as myocardial depression, systemic vasoconstriction and ventricular overdistension, reduce outflow tract obstruction.

Any hypotension during operation should be treated initially by optimizing left ventricular filling pressures using PCWP measurements as a guide to intravascular filling; the CVP is less likely to reflect changes in left ventricular volume. Where necessary, systemic vascular resistance is maintained by the use of peripheral vasoconstrictors. Inotropic agents increase left ventricular contractility and therefore may provoke additional obstruction by increasing the contractility of the abnormal muscle in the outflow tract. Beta blockers, in contrast, by suppressing sympathetic stimulation, decrease the pressure gradient and improve cardiac output. Their use in the medical management of HOCM is well-documented [3]. Esmolol is a relatively new cardiac selective beta blocker with a short half-life (9 min) when administered i.v. [5]. It has already been used in a number of situations in which beta block of limited duration is required—for example, attenuation of the sympathetic response to laryngoscopy and tracheal intubation [6], treatment of superventricular tachycardia [5] and intraoperative management of phaeochromocytoma [7]. In our patient, we found that an infusion of esmolol produced a decrease in heart rate, a significant decrease in the outflow tract gradient and an improvement in arterial pressure. Its duration of action is relatively short; the effects disappeared within 15 min of discontinuation of the infusion.

It is interesting to note the changes in the left ventricular outflow tract gradient. Before CPB, the gradient was 84 mm Hg, but after CPB it had decreased to 50 mm Hg, suggesting that surgical myomectomy had made some improvement but the patient was not sufficiently stable. Surgical opinion was that further myomectomy could weaken the septal wall, with the probability of causing a ventricular septal defect. Metaraminol was tried, but did not improve the situation. Esmolol was therefore tried because of its short half-life. After the esmolol infusion was started, the ventricular outflow tract gradient had decreased to 10 mm Hg. It was therefore decided to stop the esmolol to see if the drug had made any improvement to the gradient. After cessation of esmolol infusion, the gradient increased to 25 mm Hg and it was only after recommencing the drug that the gradient was again reduced.

PROLONGED USE OF ISOFLURANE IN A PATIENT WITH TETANUS

J. J. W. M. STEVENS, R. M. GRIFFIN AND P. J. STOW

SUMMARY

We describe a patient with tetanus, who received isoflurane for sedation to facilitate controlled mechanical ventilation. Isoflurane was administered for 34 days, resulting in a sustained serum inorganic fluoride ion concentration in excess of 50 μmol litre^{-1} and a peak serum inorganic fluoride ion concentration of 87 μmol litre^{-1}. Although these concentrations are potentially nephrotoxic, no toxicity was evident clinically. (Br. J. Anaesth. 1993; **70**: 107–109)

KEY WORDS

Anaesthetics, volatile: isoflurane. Infection: tetanus. Kidney: nephrotoxicity.

Tetanus is a condition which requires a period of long-term sedation to facilitate controlled mechanical ventilation. Isoflurane may be a useful agent for long-term sedation because of its minimal metabolism. Furthermore, the effect on the cardiovascular system may be useful to counteract the enhanced autonomic activity associated with tetanus. There are no reports in the anaesthetic literature of the use of isoflurane sedation for tetanus.

CASE REPORT

A 44-yr-old man was admitted for endoscopic surgery to the left maxillary sinus. Before operation he was noted to have difficulty in swallowing and he complained of tightening of the face and neck muscles. Surgery was cancelled and over the following 5 days he developed muscle spasm in the abdomen and legs. A diagnosis of tetanus was made; exposure to the tetanus bacillus had probably been via soil contact 2 weeks previously. The patient had not received passive tetanus immunization because of an allergic reaction to the toxoid in childhood. In his previous medical history he was known to be allergic to penicillin and non-steroidal anti-inflammatory drugs. He was an asthmatic treated with phyllocontin, becotide and salbutamol, but had never received oral steroid treatment.

The patient was transferred to the Intensive Therapy Unit and treated initially with i.v. diazepam in emulsion. In the course of the next 24 h he developed progressive difficulty with swallowing and he required elective tracheal intubation and controlled mechanical ventilation. He was sedated with continuous infusions of propofol 80 mg h^{-1}, fentanyl 70 μg h^{-1} and midazolam 5 mg h^{-1}, with atracurium 30 mg h^{-1} for neuromuscular block.

Tracheotomy was performed on day 5 to facilitate long-term ventilation. By day 21 of ventilation, requirements for propofol and fentanyl had increased to 230 mg h^{-1} and 180 μg h^{-1}, respectively. The dose of atracurium to provide adequate muscle paralysis, as assessed by peripheral nerve stimulation (Bard critical care Model 750), had increased to 100 mg h^{-1}. During this period, sedation remained inadequate by clinical assessment (modified Ramsey scale 1–2), and there was intermittent marked variability in arterial pressure and heart rate. Isoflurane was administered in an attempt to achieve better sedation and improve cardiovascular stability, using a Siemens vaporizer Model 952 and charcoal canisters for scavenging. Propofol and midazolam infusions were stopped and sedation maintained for an additional 34 days with a mean infusion of fentanyl 140 μg h^{-1} (range 100–160 μg h^{-1}) and expired isoflurane concentration of 0.8–1.2% measured with a Kontron anaesthetic agent monitor 7860. This concentration was necessary to provide adequate sedation. Isoflurane administration was stopped for a period of 48 h between days 32 and 34 of ventilation because of a shortage of charcoal cannisters. Vecuronium was substituted for atracurium on day 32 with a mean dose of 4 mg h^{-1} (range 3–7 mg h^{-1}).

Urine output was monitored hourly, serum creatinine and urea concentrations measured daily and liver function tests measured twice weekly (table I). Serum fluoride concentrations (fig. 1) were measured with a selective fluoride ion electrode (Orion, model 94-09).

On day 41, sedation was stopped to assess the need for controlled ventilation. The patient was responsive within 30 min but he subsequently developed muscle spasm requiring resedation, muscle relaxation and further ventilation. On day 57 another attempt at weaning was made. The patient regained consciousness after 1 h and after 2 h was alert, orientated and able to repeat his date of birth. However, he remained in a withdrawn state, and after 48 h, exhibited several episodes of uncoordinated muscle spasm, possibly of a convulsive nature. Although electroencephalography was not undertaken, the spasms were treated empirically

with phenytoin. The patient experienced hallucinations for a period of 5 days, but these gradually resolved. His subsequent recovery was uneventful and he was discharged from hospital 6 weeks after leaving the ITU.

DISCUSSION

Sedation, neuromuscular block and controlled ventilation are required for the treatment of severe tetanus. Tetanus may be complicated by sympathetic nervous system overactivity, with tachycardia, labile hypertension, peripheral vasoconstriction and myocardial irritability [1]. Isoflurane reduces hypertension by decreasing peripheral vascular resistance, and suppresses catecholamine release more effectively than midazolam [2]. Therefore, it seemed appropriate to sedate this patient, a known asthmatic, with isoflurane, as large doses of propofol, midazolam and fentanyl had proven inadequate. Although the quality of sedation (modified Ramsey scale 3) was improved, there was no marked improvement in cardiovascular stability after the introduction of isoflurane even though we thought that the variability in arterial pressure was caused by inadequate sedation rather than autonomic dysfunction.

We chose atracurium initially for neuromuscular paralysis because of its complete metabolism and lack of accumulation, and it has been shown previously to be useful for the management of tetanus [3]. However, after the development of a moderate degree of bronchospasm, vecuronium was substituted. Respiratory function improved, and a greater degree of haemodynamic stability was observed, in accordance with observations in a previous report of a patient with tetanus [4].

Isoflurane was administered in a greater concentration than reported previously because of patient requirement. Unfortunately, results of fluoride ion assay were not available until after discharge of the patient from the ITU. However, the serum concentration of fluoride increased during the first 72 h, as reported in a short term study of isoflurane [5]. A recent longer term study (up to

30 MAC h) showed also a continuous increase in plasma concentrations of fluoride [6]. In our patient, the plasma concentration of fluoride reached a plateau at 50 MAC h; however, only two samples were available between 300 and 700 MAC h. The serum concentration of fluoride increased again when isoflurane was discontinued. Both peaks of 87 and 83 μmol litre^{-1} occurred after isoflurane had been discontinued for 48 h (fig. 1). Metabolism of isoflurane begins with oxidation of the carbon–halogen link of the alpha carbon, leading to difluoromethanol and trifluoroacetic acid. Trifluoroacetic acid is resistant to oxidative and reductive breakdown, but difluoromethanol is metabolized to formic acid with release of two fluoride ions. In a previous study, enflurane metabolism was inhibited by administration of isoflurane [7]. Therefore, it is possible that isoflurane inhibits its own metabolism or that there are significant interindividual variations in metabolism of isoflurane.

Animal [8] and clinical [9] studies have investigated the toxicity of fluoride accumulation during methoxyflurane anaesthesia. In man, at serum fluoride concentrations greater than 50 μmol litre^{-1}, subclinical toxicity occurred, with increased serum uric acid concentration. A serum fluoride concentration exceeding 90 μmol litre^{-1} is associated with a variable degree of toxicity manifest by serum hyperosmolality, hypernatraemia, polyuria and low urine osmolality. Despite prolonged exposure to a fluoride ion concentration greater than 50 μmol litre^{-1}, our patient showed no increase in urinary volume or increase in serum creatinine and urea concentration, which might have been indicative of nephrotoxicity. This is in agreement with other reports of prolonged administration of isoflurane [6, 10].

The muscle spasm resembling convulsive activity after withdrawal of sedation is difficult to explain. Isoflurane does not have proconvulsant properties [11], and long term infusion of atracurium in a patient with tetanus has not been shown to cause excessive accumulation of laudanosine [3]. It is possible that the observed phenomenon represented residual muscle spasm, as has been described previously in tetanus [12]. Dantrolene 1–2 mg kg^{-1} has been used as a spasmolytic agent in mild and moderate tetanus, but experience is limited in severe tetanus and its use was considered inappropriate for this patient.

This case report demonstrates that prolonged administration of isoflurane is associated with potentially toxic concentrations of serum inorganic fluoride, although no clinical effect on renal function was found. This paradoxical finding indicates that further investigation into the safety of isoflurane in long term use is required before its use can be recommended.

CORRESPONDENCE

POSTOPERATIVE PAIN THRESHOLDS

Sir,—Dahl and colleagues have demonstrated a decrease in the pain threshold and an increase in subjective assessment of pain in postoperative female patients recovering from gynaecological operations [1], in contrast to a lack of alteration in a control group. The degree of hyperalgesia showed a significant inverse correlation with time after surgery. The patients had received morphine and paracetamol after operation, but not for 12 h before testing. Of relevance, however, is the fact that in all patients anaesthesia was induced with thiopentone 4–5 mg kg^{-1} i.v. Thiopentone has long been known to have antanalgesic properties in small doses [2].

Kissin and colleagues have demonstrated that barbiturates inhibit stress-induced analgesia in Sprague–Dawley rats [3]. In this study, a motor reaction threshold to noxious pressure on the tail was measured. Stressing the animal by placing a clamp on the hind paw produced an increase in reaction threshold. Pentobarbitone in subanaesthetic doses largely abolished the stress-induced increase in motor reaction threshold. Stressing the rats on recovery from thiopentone anaesthesia failed to increase the motor reaction threshold from that in the unstressed rat. This parallels the situation in Dahl's study. Wilder-Smith and Borgeat also have demonstrated a hyperalgesic response to small doses of thiopentone in unstressed patients [4]. Their study showed similar results with low-dose propofol, but neither hyperalgesia nor analgesia with etomidate.

In Dahl's study, testing was performed 40–80 h after anaesthesia. At this time, a small proportion of the anaesthetic agent remains within the circulation. This may or may not be sufficient to produce an antanalgesic effect (whether or not the antanalgesic effect is related to plasma concentration is not clear from Kissin's work). The decrease in pain threshold diminishes with time, consistent with a decrease in circulating barbiturate.

The quoted studies do not refute Dahl's findings, but it may be that the increase in postoperative pain perception and decrease in pain threshold are not caused solely by central neuronal sensitization, but that a contribution is made by residual thiopentone. It would be interesting if Dahl's findings were repeated with different anaesthetic induction agents.

PHARMACOKINETIC/PHARMACODYNAMIC MODELLING OF ATRACURIUM

Sir,—The multiple elimination pathways of atracurium from both the central and tissue compartments confound its pharmacokinetic/pharmacodynamic analysis and necessitate the use of innovative models. Three recent articles [1–3] proposed models that differ from ours [4]. I contend that each of these new proposed models is flawed.

Beemer, Bjorksten and Crankshaw [1] infused atracurium using a computer-controlled infusion regimen to estimate volume of distribution at steady-state (V^{ss}) as the ratio of the amount of drug in the body at steady-state (X^{ss}) divided by the steady-state atracurium concentration. X^{ss} was estimated as the quantity of atracurium infused minus that eliminated. However, their estimate of the quantity eliminated (the product of plasma clearance and area under the plasma concentration–time curve (0–1 h)) is flawed—it does not account completely for drug eliminated from tissue rather than plasma. Because atracurium is eliminated from both plasma and tissue, Beemer's group underestimated V^{ss}. The authors' retort that they used a non-parametric approach to avoid this problem is invalid—these non-parametric techniques require that elimination be from the central compartment only [5].

Parker and Hunter's interesting approach to relating the recovery of atracurium to its pharmacokinetics used "standard formulae" to estimate V^{ss} [2]. Yet, in their letter to the editor criticizing the manuscript by Beemer, Bjorksten and Crankshaw, they stated that for atracurium, "standard formulae...[do] not allow calculation of the...steady-state volume of distribution as usually defined" [6]. Their letter is correct, their manuscript in error—standard formulae require the assumption, invalid for atracurium, that clearance occurs only in the central compartment. As with Beemer's group, Parker and Hunter underestimate V^{ss}.

Parker and Hunter also propose a new pharmacodynamic model for atracurium in which a threshold concentration is necessary at the neuromuscular junction to produce paralysis [3]. The systematic error they observed fitting the traditional model (leading them to reject that model) may arise from their obtaining venous rather than arterial blood samples—for atracurium (as other drugs), venous concentrations obtained early during an infusion underestimate arterial and effect site concentrations [7]. Alternatively, a more complicated link model may be necessary to explain the relationship between concentrations in the plasma and those at the neuromuscular junction. However, in the absence of actual measurements of effect site concentrations, all pharmacokinetic/pharmacodynamic models describe "black boxes"; therefore, no single model can be demonstrated to be valid or invalid. Parker and Hunter claim that their model provides "explicit demonstration of a margin of safety of neuromuscular transmission in the human". Yet, the margin of safety associated with their model ($C_{threshold} = 159$) differs little from a concentration (120 ng ml^{-1}) that I calculate produces minimal (1%) twitch depression with the traditional model. Perhaps these investigators should evaluate their model using a more appropriate data set (arterial plasma concentrations) before rejecting a well accepted (and parsimonious) model.

Our model for atracurium [4] is the only one to incorporate Dr Hull's editorial suggestion that atracurium's pharmacokinetics can only be determined if the rate of elimination from the peripheral compartment is estimated [8]. Although our model may be flawed, to date no one has presented a cogent argument regarding any errors. I am delighted that this topic has elicited so much interest in the anaesthesia research community, but I believe that errors by these other investigators should be corrected.

8. Hull CJ. A model for atracurium? *British Journal of Anaesthesia* 1983; 55: 95–96.

Sir,—The criticism by Dr Fisher of our method to calculate the V^{ss} of atracurium is the same as that previously raised by Parker and Hunter [1, 2]. We agree that our method does underestimate the true V^{ss}. However the V^{ss} we derived, which perhaps can best be termed the "apparent" or "functional" V^{ss}, is that which is required in conjunction with our estimate of the total clearance of atracurium at steady-state, for design of a bolus–infusion regimen [3]. We contend that derivation of parameters which predict dosing requirements is the primary goal of pharmacokinetic research. The true V^{ss} has no clinical use, as the time-dependent changes in the clearance of atracurium cannot be measured directly, and any hypothesized estimate may be the result of a significant modelling error.

The pharmacokinetic parameter estimates derived from the model proposed for atracurium by Fisher and colleagues are erroneous [4]. The slow initial sampling rates were insufficient to allow the model to take into account the contribution of the rapidly degraded isomers of atracurium [5]. Our own unpublished observations are consistent with those reported in the latter paper and suggest that 22.5% of the total dose of atracurium, components of the cis–trans and trans–trans isomers, undergo very rapid degradation in blood. The errors caused by the slow sampling rate were compounded by Fisher and colleagues using only samples obtained 25 min after the addition of atracurium in the analysis of their *in vitro* data. The contribution from these rapidly degraded isomers to the *in vitro* degradation of atracurium was totally neglected.

Sir,—We thank Dr Fisher for the interest which he has shown in our recent articles in the *British Journal of Anaesthesia* [1, 2], and we are grateful for the opportunity to reply. Dr Fisher raises two main points of difficulty: first the calculation of V^{ss}; second, the formulation of the new, threshold, pharmacodynamic model.

The calculation of V^{ss} as usually defined is, as Dr Fisher points out, subject to difficulties because of the elimination of atracurium from sites outwith the sampled (plasma) compartment, and the solution of this difficulty would require knowledge of the extent of peripheral degradation of the drug. This still remains unknown, although Fisher has estimated the rate of peripheral degradation from the rate of degradation in plasma *in vitro*. Whilst his approach may well represent an advance over methods which do not use such a correction, we have at least two reservations concerning it. First, atracurium undergoes ester hydrolysis to some extent, and the activity of esterases in tissues may not be identical to the activity of esterases in plasma. Second, the greater concentration of proteins in plasma than in interstitial fluid ensures a distribution of diffusible ions which falls short of equality, with a greater concentration of hydrogen ions in the plasma than in the interstitial fluid [3].

We agree with Fisher that our estimates of V^{ss}, in common with those of Beemer, Bjorksten and Crankshaw [4], are subject to error on this account, and it was for this reason that we stated exactly how we obtained the values of V^{ss}, and that these are estimates ([2] "Data analysis", paragraph 3). We do not feel that this seriously calls into question the utility of the results in the context of that paper, for the standard formula for V^{ss} at least allows standardized comparison of the data in volume terms. The purpose of the paper was to demonstrate, across a range of individuals, that drug effect is dependent on disposition. This is almost routinely assumed to be the case for the non-depolarizing neuromuscular blocking drugs and, of course, is implicit in the attempt to formulate a pharmacodynamic model. Direct evidence on this point is, as we pointed out in the introduction to the paper, rather scant, and the demonstration which is given in our paper of the correlation between the pharmacokinetic and pharmacodynamic data sets materially adds to the evidence which is available in this paradigm.

The second area of interest is the threshold term of the pharmacodynamic model, concerning which Dr Fisher raises several points:

(1) We agree that it would have been preferable to have used arterial rather than venous blood samples. We did not do so because the patients we studied were healthy, and were not about to undergo very major surgery. However, we must correct the suggestion that the systematic error in fitting the standard model is an artefact arising from the use of venous samples. On the contrary, venous samples *underestimate* the arterial plasma concentration to which the site of action is exposed during onset, for two reasons: first, because they are "downstream" at a time of increasing plasma drug concentration; second, because extraction of drug by the tissues ensures that venous concentrations are smaller than arterial during onset of block. If anything, the site of action was exposed to a *greater* drug concentration than that which we measured, during the period of the "onset discrepancy". Any systematic error arising from the use of venous samples thus militated against the discovery of a threshold, and we would have perhaps found a stronger case for postulation of a threshold, and greater values of $C_{\mathrm{P}}^{ss}{}_{0}$, had we used arterial samples.

(2) Perhaps the most important point concerns the calculation which Dr Fisher presents of the effect of the drug at a concentration close to our estimate of $C_{\mathrm{P}}^{ss}{}_{0}$. We agree that a concentration of 120 ng ml^{-1} produces little twitch depression, and this is predicted by the standard model, *if* one assumes a value of gamma approximately 4. For example, if one applies a concentration of 120 ng ml^{-1}, mentioned by Dr Fisher, to the standard logistic equation, with a $C_{\mathrm{P}}^{ss}{}_{50}$ of 360 ng ml^{-1}, and gamma of 4, then:

$$\text{Effect} = \frac{120^4}{120^4 + 360^4} \times 100 \approx 1.2\%.$$

The value of gamma which Dr Fisher must have used in his calculation is close to what one obtains if one fits the standard model. Unfortunately, to fit an inappropriate model may lead to inappropriate parameter values, and it is precisely gamma which decreases in value when one restructures the standard model to include a threshold. The greater values of gamma which are obtained with the standard model are the means by which the standard model obtains a small value of effect when effect site concentrations are relatively great. We can see no other reason for proposing or holding onto such a value of gamma, whilst we can see good reasons for proposing a threshold.

(3) Whilst effect site concentrations are hypothetical, and pharmacokinetic and pharmacodynamic models may represent "black boxes", we do not agree that they are black boxes of an entirely arbitrary structure. In our view, structural and statistical aspects of model building should go hand in hand. To accept the nihilistic suggestion that no single model can be valid or invalid implies that we should abandon the structural aspects of model building altogether and simply fit, say, a polynomial to our data set. This would, however, fail to advance our understanding of what factors are quantitatively responsible for drug actions, and we do not feel that Dr Fisher would seriously entertain this logical conclusion of his proposition.

(4) Dr Fisher makes the interesting suggestion that a more complicated link model might be necessary to explain the

relationship between plasma concentration and effect. We would agree that the assumption of first-order intercompartmental drug transfer is a simplification of what must obtain in the muscle *in vivo*, and it may be that further refinement of the link model will bring closer agreement between observations and model predictions. Such refinement would add further model parameters, and, in our view, these will require simultaneous justification from both structural and statistical points of view.

We are delighted by the interest which Dr Fisher has shown in our work, but we fail to see that there is a flaw in the justification for the threshold model which we have proposed.

SEDATION WITH PROPOFOL DURING REGIONAL ANAESTHESIA

Sir,—Diprivan (propofol) has been used extensively to sedate patients undergoing procedures with regional anaesthesia. However, its use to provide sedation, as distinct from anaesthesia, in association with regional anaesthesia is not an approved indication in every country. Recent unpublished information [1] has indicated that, in some instances, sedation with propofol in patients given regional anaesthesia for surgical procedures can be associated with bradypnoea or hypoxaemia, or both. A reduction in oxygen saturation has been reported by Patterson and colleagues in patients given propofol for sedation whilst undergoing upper gastrointestinal endoscopy [2]. In view of these observations, oxygen saturation should be monitored in all such patients, with oxygen supplementation readily available for provision where clinically indicated.

ICI also wish to remind clinicians that propofol should be given only by those trained in anaesthesia and not those directly involved in the conduct of surgical or diagnostic procedures.

ASPIRIN, BLEEDING TIME AND CENTRAL NEURAL BLOCK

Sir,—We write in support of the views expressed by Drs O'Kelly and Lawes [1] on the limited usefulness of the bleeding time as a clinical screening test in patients receiving aspirin therapy who are candidates for central neural blocks. Our own detailed views have been published elsewhere [2] and we shall not repeat them here. However, we are concerned that Dr McDonald maintains her dogmatic support [3] of the use of the bleeding time and that Professor Bromage suggests that it may be medico-legally imprudent not to perform this test [4]. We would remind them that there are two entirely separate matters being considered here. First, does aspirin therapy increase the risk of spinal haematoma? Second, is the bleeding time a clinically useful indicator of the amount of platelet dysfunction produced by aspirin therapy? Even if the answer to the latter question is in the affirmative, this does not imply that aspirin therapy increases the risk of spinal haematoma. That question can only be answered by long-term epidemiological studies. At the moment there are no data, only opinions.

DEATH CERTIFICATION

Sir,—I found Dr Baskett's review of cardiopulmonary resuscitation helpful and informative [1]. However, he perpetuates a common misconception about certification of death. He states that (non-medical personnel) "are not qualified to certify death". In the U.K., this is incorrect. If Dr Baskett cares to examine a death certificate, he will find that there is still space to indicate that the body was not seen after death by a medical practitioner. Statements such as his will encourage bystanders, professional or not, to undertake futile, undignified and psychologically hurtful cardiopulmonary resuscitation when it is plain that it would be pointless.

It is unhelpful for an expert reviewer to preach the uncritical application of cardiopulmonary resuscitation, which is already widespread and too often inappropriately attempted.

A. C. Skinner
Warrington

1. Baskett PJF. Advances in cardiopulmonary resuscitation. *British Journal of Anaesthesia* 1992; **68**: 182–193.

Sir,—Thank you for asking me to comment on Andrew Skinner's letter. He may be technically correct in his review of the contents of the death certificate. However, I was dealing with the reality of U.K. practice, particularly with nurses in hospital who require prior instructions from a senior doctor in charge of the patient before implementing a "do not resuscitate" order. I was urging that consultants and other senior doctors make such a decision before their patients suffer cardiac arrest, and communicate their instruction to the nursing staff. Doctors would seem to be abandoning their responsibility if they left such decisions to the nursing staff. More extensive use of a hospital "do not resuscitate" policy for patients in whom resuscitation is inappropriate should go some way towards achieving Dr Skinner's (and my own) aim of reducing the number of futile and undignified resuscitation attempts.

The situation outside hospital is slightly different because, in the majority of cases, prior medical instructions have not been issued. There may be a few instances in which the family doctor has given guidance to the relatives. However, I believe that the ambulance service, in the absence of knowledge of the patient's prior health status, should be instructed to proceed with resuscitation with the exception of obvious cases such as decapitation, incineration or rigor mortis, *etc*.

KETOROLAC POSTOPERATIVE ANALGESIA

Sir,—I read with interest the article "Ketorolac for postoperative analgesia after orthopaedic surgery" [1]. Currently, we are undertaking a similar study investigating the morphine-sparing effect of ketoprofen after total knee replacement. I wish to make the following comments:

First, a fixed i.m. dose of morphine is not the ideal way to determine the amount of opioid needed to investigate a morphine-sparing effect of any drug [2]. The total dose of morphine given by this route is dependent on patient–nurse communication and nursing response, and this is mentioned in the discussion [1].

The aim in any pain study is to test the severity of pain and quality of pain relief experienced by the patient during the postoperative period. Two assessments of pain over 24 h may not be enough to give an adequate idea of the quality of pain. Baseline assessment at the time of arrival from theatre, before any analgesic injection is given, is essential. Pain relief scores at more frequent assessments should have been added (beside visual analogue (VAS) and verbal pain scores) to improve the sensitivity of these tests in detecting the amount of resulting pain relief.

From baseline assessments, the pain intensity difference (PID) and summed PID could have been calculated, both of which have been shown to be more sensitive [3] in revealing significant differences when VAS failed to do so.

Last, controlling another factor—the nature of the operation—might be prudent in any controlled pain study. The authors did not specify the type of operations, but classified them as only major and minor surgery according to specific criteria. These do not rule out the possibility of patients within the same category having a different quality of pain.

A. AL-HASANI
Leicester Royal Infirmary
Leicester

3. Power I, Noble DW, Douglas E, Spence AA. Comparison of i.m. ketorolac trometamol and morphine sulphate for pain relief after cholecystectomy. *British Journal of Anaesthesia* 1990; **65**: 448–455.

Sir,—It is true that the use of a fixed i.m. dose of morphine is not the ideal method to study the morphine-sparing effects of a drug. Ketorolac has been shown to produce a morphine-sparing effect in other studies. The study in question was designed to see if there was any significant reduction in the use of morphine when this was prescribed in the usual manner in our hospital after orthopaedic surgery. This approach may be more relevant to clinical practice, as the use of patient-controlled analgesia is unlikely to be the standard method of providing analgesia for all patients in the near future.

I am surprised at the suggestion that pain measurements should have been made before any analgesics were given. All patients received intraoperative morphine and either ketorolac or placebo at the end of surgery, as we felt that to withhold analgesia for the purpose of studying pain would be unethical. The use of more frequent pain assessments may be of value, but could also influence the patient's demand for analgesia. This study aimed to reproduce the routine postoperative care as closely as possible, whilst making sufficient observations from which valid con-

[redacted]

arean section under general anaesthesia but her medical history was otherwise unremarkable, with no history of opioid abuse. Preoperative assessment included instructions on the use of a PCAS for postoperative pain relief.

Intraoperative management with spinal anaesthesia was uneventful, with no complaint of discomfort during the procedure. A PCAS (Graseby) was attached to the patient's i.v. infusion with an Abbott Mini-Bore PCAS giving set. The PCAS was loaded with a 50-ml syringe containing morphine sulphate 2 mg ml^{-1}. It was programmed with a bolus dose of 1 mg, a lock-out time of 3 min and no background infusion.

Eight hours after the operation, anaesthetic advice was sought, because there was only 6 ml of solution remaining in the syringe. The patient was fully conscious, with a ventilatory frequency of 16 b.p.m. She still complained of slight pain on movement, but none at rest.

The PCAS chart revealed that the patient had used 89 mg of morphine over the 8 h after surgery. The consumption per hour was as follows: first 1 h 12 mg, second 1 h 3 mg, third 1 h 25 mg, fourth 1 h 16 mg; over the next 4-h period another 33 mg of morphine. No programming error was found on the PCAS. There was no evidence of extravasation of morphine. At this stage, the patient admitted to giving the hand device to her husband during visiting, and had asked him to press the switch every 3 min. It had seemed an ideal way of getting good analgesia without having to rouse herself from slumber to press the switch.

The patient was warned how inappropriate and potentially dangerous this practice is. The PCAS was refilled and reprogrammed with a lock-out time of 6 min. The nursing staff were asked to watch for ventilatory depression, and the patient was monitored with a pulse oximeter. She remained pain free at rest and only had slight pain on movement over the next 16 h. She consumed an additional 21 mg of morphine. Sp_{O_2} remained at 97% with FI_{O_2} 0.28.

This case differs from others reported [2, 3] in that the patient required no resuscitation, and the unusually large dose of opioid was administered by her husband. This case demonstrates that we must continue to emphasize strongly that the P in PCAS means patient and not by proxy.

VETERINARY USE OF "XYLOCAINE" SPRAY

Sir,—The Association of Veterinary Anaesthetists wishes to draw attention to a problem experienced in cats with the new formulation of the pump pack Xylocaine Spray (Astra Pharma-

USE OF THE LARYNGEAL MASK AND FACE MASK BY INEXPERIENCED PERSONNEL

Sir,—Tolley, Watts and Hickman have demonstrated apparently that the laryngeal mask airway (LMA), when inserted by inexperienced personnel, is less satisfactory for ventilation of the lungs than use of a traditional mask and airway [1]. We believe that their results warrant careful examination, because they conflict with previous studies which demonstrate that LMA insertion is learned readily by inexperienced personnel [2, 3]. There are some features of the study that cause us some concern and may make the results less valid than they might have been.

Although the operators are stated to be junior hospital doctors with no postgraduate anaesthetic experience, there is no information on whether or not they had received resuscitation training, either when medical students or after qualification. We understand from the several Australian trainees in our department that it is common practice in Australian medical schools for undergraduates to undergo basic resuscitation training which includes the use of bag and mask ventilation.

Patients who were likely to present difficulties for tracheal intubation were excluded. We would be interested to know what criteria were used and if any of the patients included in the study actually presented difficulty when the trachea was intubated after the study manoeuvres were completed (this is a situation in which the LMA has a well recognized role) [4]. It is not stated how the operators were instructed to use the face mask and airway. Use of a mannequin or demonstration *in vivo* may make the technique easier to learn than using a video. Also, the operators were not taught in a standard fashion to use the LMA: some watched a video, while others were demonstrated the technique by an investigator.

Patient selection and anaesthetic management were not strictly standardized, with a large age range of 18–84 yr (ASA I–III) and there was no direct monitoring of the state of neuromuscular block. The spread of patient age and general health may not directly affect results in this study; however, we are concerned that there was no standard muscle relaxation, when variations in muscle tone could affect the ease of ventilation by inexperienced personnel using each technique.

Although the required tidal volume of 800 ml was recommended by the American Heart Association, the source of the time limit of 40 s is not mentioned. We are intrigued by the decision to record the times of all the failures as 41 s and then quote the results as a mean time to successful ventilation. Additional useful information would have included the ranges of the time to successful ventilation. Although the difference in mean times to ventilation is statistically significant, it is interesting to debate if the approximately 5-s delay with the LMA is clinically significant, bearing in mind the "hands free" security of the airway and the degree of protection against aspiration that the LMA potentially affords. It would also be interesting to know the exact causes of failure in both groups. Was it desaturation to less than the limit of 95 %, or was it difficulties with LMA placement (or the fit of the mask in the other group)?

The fact that each operator managed the airways, using both techniques, of five patients would enable the authors to examine the learning curve for each technique. We would be interested to know if there was any reduction in time taken to successful ventilation as experience was gained and, if so, if the improvement was equal with each technique.

This study compared LMA ventilation and use of the mask and airway yet, during resuscitation, initial ventilation is with the face mask and airway using a large inspired concentration of oxygen. The next phase is to control and protect the airway by intubating the trachea with a tracheal tube. The exact role of the LMA in resuscitation has yet to be elucidated fully, but we feel that it is possible that the LMA may be a useful adjunct for airway management, especially when the operator is inexperienced. The degree of protection against aspiration afforded by the LMA and its stability within the airway during external cardiac massage need to be determined. We hope that the questionable results of this study will not deter investigators from examining in more detail the exact role of the LMA during resuscitation.

4. Benumof JL. Management of the difficult adult airway. *Anesthesiology* 1991; **75**: 1087–1110.

Sir,—Tolley, Watts and Hickman [1] compared ventilation with the laryngeal mask and face mask by inexperienced personnel. Their data do not support the statement appearing in the summary that "the LMA cannot be recommended as a resuscitation device for use by inexperienced operators". Having failed to address most of the relevant questions, they are quite unjustified in making categorical statements about the place of the LMA during cardiopulmonary resuscitation.

Some of the *theoretical* advantages of the LMA compared with the Guedel airway and face mask during cardiopulmonary resuscitation are as follows: avoidance of anatomical airway obstruction, maintenance of a seal between the device and the airway and freeing of the operator's hands for other activities (such as cardiac massage, cervical spine control and two-handed bag squeezing). Therefore, ventilation *should* be greater *in the long term*, particularly by the single operator. None of these issues has been addressed adequately by Tolley and colleagues, who have examined the first 40 s of ventilation only, without cardiac massage or resuscitation.

Against these supposed advantages must be balanced the disadvantages of the LMA, namely: the time necessary for insertion and the resultant loss of ventilation, the difficulty of insertion, the possibility of a greater risk of aspiration of stomach contents [2] and the loss of the airway seal when compliance is reduced, such as during external cardiac compression.

Success rates of 74 % and 92 % are reported for the LMA and face mask groups, respectively, and it is inferred that the reason for failure to achieve two tidal volumes of 800 ml within 40 s in the LMA group was delayed insertion. We have recorded an LMA insertion rate of 94 % by inexperienced operators within the same time, using the production of carbon dioxide as the end-point [3]. This suggests that Tolley's junior doctors were inadequately trained or were particularly unskilful, or that our results were inaccurate. Our trainees carried out twice the number of insertions and their performance was very similar to that recorded for anaesthetists on first exposure [4, 5]. We do not believe that our results are inaccurate. Despite the lack of a significant learning curve for LMA insertion [3], it is still necessary to include at least some "hands-on" experience during training. Additionally, as junior doctors, they would have had much more practical experience of ventilation with a face mask than with an LMA. Therefore, it would seem that Tolley's high LMA failure rate represents inadequate training and that, if a more realistic success rate had been achieved, the difference recorded between techniques would have been substantially reduced and perhaps eliminated.

Not only should the study have been carried out after adequate training, rather than during it, but it should also have been extended over a clinically relevant period—for several minutes—when insertion has been successful within 40 s. It is possible that the LMA would allow more ventilation than the face mask over a longer period, making good the losses necessitated by insertion, as known from the inadequacies of single operators using a face mask, Guedel airway and resuscitation bag [6, 7].

This study poses an important question, but as a result of both failure to train adequately and an inappropriate period of assessment, its conclusions are not justifiable. The LMA may or may not be useful during resuscitation, but more carefully conducted research is needed before it is written off for this purpose.

Sir,—We are grateful for the opportunity to reply to the points made in these letters. The aim of the study was to assess the use of the LMA by inexperienced operators with the intention that it be available on general wards for use by nurses and junior doctors in emergencies. Training these large numbers of staff to use the device would necessarily be brief. The operators in our study had all trained at the same medical school and had received a short period of resuscitation training as undergraduates. This usually involved only a small amount of "hands on" experience of airway management. However, our proposed users in emergencies on wards would all be expected to have had a similar small amount of previous experience with face mask and bag, and perhaps none with patients. The inexperienced operators to whom Dr Tighe refers were naval medical trainees who had a short training programme using mannequins. The fact that the success rates differ reflects only that different populations were studied, and no inaccuracy need be invoked to explain it. With the LMA, his inexperienced group performed as well as anaesthetists, and ours did not. The group we used and the training given seemed to us to be a reasonable representation of the final ward users and the depth of training they can expect.

No specific criteria were used to exclude patients who might present with difficult tracheal intubation, but the investigators who recruited patients erred on the side of caution in their choice. None of the patients presented difficulty with intubation subsequently. Operators were shown how to use the mask and airway by demonstration by one of the investigators. Although the means of demonstration, age ranges and degree of neuromuscular block were not standardized, we feel that the crossover design of the study, with each patient being subjected to both airway management techniques in random order, effectively excluded any potential bias caused by these factors.

Reasons for failure in the mask group were not recorded, but were mainly as expected: an inability simultaneously to maintain a seal and a clear airway. All the failures in the LMA group were caused by jamming of the mask at the posterior pharyngeal wall. Times and failure rates for the first and fifth attempts for each operator were not statistically different, so no learning effect was demonstrated. It is of interest that in only two patients was the LMA successful where the face mask had failed, whereas there were 11 patients in whom the reverse was true.

The source of the 40-s cut-off time was the paper by Davies and colleagues [1]. We agree that 40 s is a very short time; however, for reasons of patient safety the time was accepted to reduce the risk of desaturation. As there were no episodes of desaturation during the trial, a less conservative time might be allowed in future. The ranges of times were 15–40 s for the LMA and 14–40 s for the bag and mask. We felt that, although a difference in mean times of only 5 s is probably not clinically significant, the difference in failure rate was. In other words, the added long-term advantage of the LMA is lost if it cannot be inserted at all. It is possible that this difference would disappear if more time was allowed, but are we going to advise users to persevere with attempts to insert the LMA after 40 s without success when the patient is apnoeic, while with the face mask they may have delivered two or three breaths of 100% oxygen in this time?

Our conclusion was based on the results and conditions in this trial, which were intended to imitate use by inexperienced ward staff with minimal training. We believe that the results indicate that the LMA is not suitable as a first line airway management tool to be used by staff who have had only a brief demonstration of its use. This does not preclude its use as a second line of management by staff with more training, as in the paper by Davies and colleagues [1].

We agree that the LMA deserves further consideration for emergency airway management, for the reasons given. Further work might also define if the use of expired tidal volumes, as in our paper, or detection of end-tidal carbon dioxide as in the paper of Davies and colleagues, is a more accurate measure of adequate ventilation.

CHANGES IN HAEMODYNAMIC VARIABLES WITH THIOPENTONE, METHOHEXITONE, PROPOFOL AND ETOMIDATE

Sir,—I read with interest the paper by Price and colleagues [1], and I agree that their results may indicate that etomidate produced some degree of myocardial depression, as has been shown by other investigators [2, 3]. However, I believe that their study design precludes comparison with other induction agents because they did not account for the effects of either changes in blood-gas tensions or the accompanying medications (nitrous oxide and alfentanil).

Both hypoxaemia and hypercapnia may increase cardiac output and decrease systemic vascular resistance. Because thiopentone, methohexitone and propofol depress ventilation more than etomidate [4, 5], the different results in these groups possibly could be explained by hypoventilation and hypoxaemia. This could have occurred in these patients, as $F\text{I}_{O_2}$ was 0.3, ventilation was assisted only after 30 s of apnoea and, because there was no documentation that either ventilatory frequency or tidal volume were measured, it seems possible that both could have been less than optimal for the maintenance of normal blood-gas tensions.

Also, the combination of alfentanil and nitrous oxide may have depressant effects on cardiac output [6] and should have been used as a control to establish if the effects in the etomidate group were attributable to the administration of these drugs. Until the above issues are addressed, I believe that the conclusions drawn from their results are probably invalid.

Sir,—Thank you for the opportunity of replying to the comments of Dr Williams. The design of a study to examine cardiovascular changes during induction of anaesthesia is difficult. Our initial aim was to examine the effects of the anaesthetic induction agents alone. Our pilot study showed that doses of the induction agent sufficient to induce anaesthesia in unpremedicated patients resulted in anaesthesia of less than 3 min. We decided therefore to supplement anaesthesia with other agents used commonly in clinical practice. As supplementary drugs were given to all study groups, we feel that the observed pharmacological differences may be interpreted as those produced by the anaesthetic induction agents.

The ventilatory differences between the drugs used in our study again make study design difficult. Hypoxaemia and hypocapnia produce cardiovascular effects, although I am uncertain of their relevance over the time scale of our study. Intermittent positive pressure ventilation (IPPV) also produces cardiovascular effects. To minimize this between drugs with differing ventilatory depressant effects, an apnoeic period of 30 s was chosen.

Increases in Pa_{CO_2} over the period of the study are unlikely to have been significant, as ventilation was assisted using a Bain circuit with a high fresh gas flow to minimize rebreathing. A pulse oximeter was used in the majority of patients and hypoxaemia, which occurred rarely, was transient.

ANTEPARTUM ASSESSMENT FOR ANAESTHESIA

Sir,—In response to the letter by Cody and Johnston [1], we offer our solution for reducing the likelihood of unanticipated anaesthetic problems occurring out of hours when senior help may not be readily available.

In our department, a simple card file system has been in operation for the past 10 years. This was initiated after episodes of "failure of communication" occurred, the obstetricians being reluctant or insensitive of the need to divulge information relevant to the potential anaesthetic management of an obstetric emergency. However, the problem of communication between anaesthetic staff was also found to be at fault in several cases. Patients are entered into the card file via three main routes: (1) At antenatal clinic where the obstetrician identifies a potential anaesthetic risk or problem, such as previous lumbar laminectomy, scoliosis, major neurological, cardiovascular or respiratory disease. (2) Patients attending the antenatal clinic who volunteer information concerning problems that have occurred during previous surgical procedures or confinements at other hospitals, for example pseudocholinesterase deficiency, bleeding disorders, or complicated extradural placement. (3) Patients who have had unanticipated complications in their anaesthetic management in our own department, such as problems establishing extradural or subarachnoid block, difficult or failed intubation, allergy or anaesthetic drug sensitivity.

In the first two cases, patients are seen during the same antenatal clinic visit by a member of the anaesthetic department, usually a consultant. The potential problem is established, and an outline plan for their management is recorded on a filecard with basic obstetric details, including likely date of confinement. The period after consultation permits correspondence with other hospitals to obtain old notes and to request appropriate specialist advice. In the third instance, details of the anaesthetic problem encountered and its solution are recorded in case of a future confinement.

The merit of this simple system is that it is easy to use and update. It is available in the anaesthetic office area adjacent to the delivery suite theatres, and trainee anaesthetists are encouraged to browse through the card file. "Pending" problems (those patients approaching term) are filed separately at the front of the file; other cards are filed alphabetically. Any patient whose name appears on our card file system is issued with a yellow sticker which is applied to the front of their notes. This indicates that when the patient is admitted the on-call anaesthetic staff are to be informed. After delivery, in the event of anaesthetic intervention, the nature of the management and the outcome are recorded by the attending anaesthetist. Equally relevant is the observation that no anaesthetic involvement was required.

We have found that, in a hospital with approximately 6600 deliveries annually, we have successfully reduced, but not eliminated, the incidence of the 'phone call which concludes "and by the way..."

1. Cody MW, Johnston JA. Antenatal assessment for anaesthesia. *British Journal of Anaesthesia* 1992; **69**: 332.

Sir,—I have every sympathy with Drs Cody and Johnston [1] over their difficulty in persuading obstetricians and midwives to refer expectant mothers with medical problems for anaesthetic consultation. The need for *antenatal* referral, for example for diaphragmatic hernia or congenital heart disease diagnosed *in utero*, is much rarer. To achieve prompt referral for a *maternal* problem, two hurdles must be overcome. First, those seeing the mother during pregnancy must spot the problem and, second, the need for anaesthetic referral must spring to mind. It is a sad fact that in many centres one or both of these hurdles may not be overcome, possibly because a mother may rarely see an obstetrician or visit hospital for antenatal care. Nevertheless, to see *every* booked mother would be a major undertaking in many units, beyond the scope of anaesthetic departments.

I attempt to solve the problem by writing an angry letter every time we are taken by surprise as were Drs Cody and Johnston, and by setting aside a regular time each week for anaesthetic referral.

1. Cody MW, Johnston JA. Antenatal assessment for anaesthesia. *British Journal of Anaesthesia* 1992; **69**: 332.

Sir—Thank you for the opportunity to reply to Dr Reynolds' letter.

The problem of mothers not attending for antenatal visits is, I believe, beyond the anaesthetic remit. However, with the greatest extradural rates up to 50% and with an increasing Caesarean section rate there may be a case for seeing mothers antenatally. I wonder if informed consent or explanations given in the heat of labour would be valid in the current litiginous era.

BOOK REVIEWS

Adult Respiratory Distress Syndrome. Edited by A. Artigas, F. Lemaire, P. M. Suter and W. M. Zapol. Published by Churchill Livingstone, Edinburgh. Pp. 535; illustrated; indexed. Price £90.00.

This multi-author book on the *Adult Respiratory Distress Syndrome* (ARDS) brings together more than 100 contributors, 75% of whom are based in Europe and the remainder in North America. The book is divided into sections on Clinical Aspects, Morphology, Pathophysiology, Lung Water, Pulmonary Circulation, Pulmonary Function, Mechanical Ventilation, Therapy and Future Trends. It was astonishing to find that no definition of ARDS was given until chapter 47, the last chapter in the book. It was also surprising to read the old chestnut in the third line of the first chapter that there are 150000 cases of ARDS per annum in the U.S.A.—this oft-quoted guess made in 1972 puts the incidence of ARDS 10 times greater than that found in recent surveys—not a reassuring start to an authoritative text.

There was little new material in the section on morphology, although there was a very good chapter by Bachofen and colleagues with beautiful electron micrographs showing extensive destruction of the alveolar epithelium. This was followed by a good section on pathophysiology, with eight chapters on various aspects of this important subject. However, despite the fact that there were good reviews by well known workers in the field, all had the patina of age with few, if any, references after the early 1980s. The section on lung water content and capillary circulation was disappointing; in spite of the compelling evidence that alveolar epithelial destruction is the cardinal feature of ARDS, chapter after chapter discusses *microvascular* permeability. There was little or no discussion of corticosteroids, surfactant, nitric oxide, lung repair or of active transport across the alveolar capillary barrier. Reflection coefficient was not indexed and was mentioned only superficially. Permeability of the alveolar capillary barrier was also not indexed, and there was no mention of studies published in the past 6 years on barrier permeability in ARDS to ^{99m}TcDTPA or labelled albumin. The remainder of the book included a number of essays of interest to a few specialized workers who are already *au fait* with this work.

The penultimate and final chapters are likely to be of most interest to clinicians, although the section on future trends was rather dated. The reviewer concluded that the book is out of date and consequently cannot be recommended. A review article on ARDS published in this journal 2 years ago provides a more useful contemporary *résumé* of the subject.

J. G. Jones

Collection d'Anesthésiologie et de Réanimation, Volume 30: Monitorage Non-Invasif en Réanimation. Edited by G. Annat and F. Clergue. Published (1992) by Masson, Paris. Pp. 168; indexed; illustrated. Price FFr 275.00.

Since the publication of the first volume in 1984, the *Collection d'Anesthésiologie et de Réanimation* has compiled an excellent series of monographs on various topics in anaesthesia and intensive care. It is probably one of the most common books which French speaking anaesthetists read to keep up with the most recent trends in their specialty.

Monitorage Non-Invasif en Réanimation, Volume 30 of the collection, is no exception. It covers most aspects of non-invasive monitoring of critically ill patients in 10 chapters. These chapters provide good reviews on cardiovascular (four chapters) and respiratory (six chapters) monitoring.

The topics covering non-invasive measurement of cardiac output (J. L. Vincent) and the use of echocardiography in intensive care (F. Jardin) are excellent and very informative. I thoroughly enjoyed the chapter on the continuous measurement of $\dot{V}O_2$ and $\dot{V}CO_2$ during mechanical ventilation. Metabolic monitoring of critically ill patients undoubtedly will change the whole concept of nutritional management of intensive care patients.

However, the book seems to lack a chapter on non-invasive monitoring of the central nervous system, even if I do understand the Editors' choice in limiting the book to cardiovascular and respiratory monitoring. What I also found annoying was the multitude of spelling mistakes throughout the book, especially in the reference section.

On the whole, this is a book which I would gladly recommend to those with an interest in intensive care. It should be particularly useful for the trainee anaesthetist (at least those who are fluent in French) for the clinical measurement part of the Fellowship exam.

B. Appadu

MCQs in Anaesthesia: Basic Sciences. Edited by B. Kumar. Published by Butterworth-Heinemann Ltd, Oxford. Pp. 226. Price £12.95.

The aim of this book is to provide practice multiple choice questions for candidates preparing for the Part 2 F.R.C.Anaes. examination in pharmacology and physiology. The book contains 366 five-part questions. The answers and a brief explanation are provided on the reverse side of each page.

The questions are divided into nine sections covering the central nervous system (123 questions), cardiovascular (66), respiratory (56), endocrine (42), gastrointestinal (16), renal and hepatic (22) systems, and the topics haemopoiesis (14), acid–base status (17) and statistics (10). Within each section there are pharmacology and physiology questions. The distribution of questions seems reasonable and the standard of difficulty is appropriate. In the CNS section, there are 96 pharmacology questions and only 27 physiology, but pharmacokinetics, local analgesics and muscle relaxants are also included in this section. In the other sections, the balance between physiology and pharmacology is better, although the important subject of the cardiovascular system has only 66 stem questions.

This book would benefit from an introduction describing the negative marking system and providing some evidence on answering technique and self-testing. In general, this is a useful book for candidates preparing for the Part 2 F.R.C.Anaes. examination and I would recommend it to them.

C. S. Reilly

Key Topics in Anaesthesia. Edited by T. M. Craft and P. M. Upton. Published by Bios Scientific Publishers, Oxford. Pp. 298; indexed. Price £14.95.

The stated aim of this book is to provide an outline of subjects encountered commonly in the Part 3 F.R.C.Anaes. examination.

The book addresses 100 topics, listed alphabetically, which the authors suggest are common topics in the examination. Each subject is covered in 2–3 pages in a problem-oriented manner and the anaesthesia problems are dealt with under a series of headings. Suggested further reading is given at the end of each topic and consists of one or two key references.

The scope of this book is rather ambitious, with two authors attempting to provide comprehensive and authoritative summaries on a very diverse range of subjects. On reading some of the subjects with which I have clinical involvement, I found some areas where the information was inadequate and, in the case of carcinoid, outdated.

I am unsure of the role of this book. It is certainly no basis for preparation for study for the Part 3 F.R.C.Anaes. examination, as it does not cover all the subjects. Any candidate preparing for the examination will have to undertake their own background reading of all the subjects. Making use of this book would be rather like using someone else's notes—always an unsatisfactory method. The possible value of this book is as a check that a subject has been covered, or as a comforter immediately before the examination for last minute reference.

C. S. Reilly

Hypoxia, Metabolic Acidosis and the Circulation. Edited by A. I. Arieff. Published (1992) by Oxford University Press, Oxford. Pp. 215; illustrated; indexed. Price £45.00.

The quality of this series of monographs from the American Physiological Society is such that one comes to expect that they will be comprised of definitive up-to-date reviews of the chosen field. In this present volume on various aspects of the biochemical and physiological consequences of hypoxia, the reviews are as usual exhaustive and authoritative, but not always up-to-date. The book springs from a FASEB meeting in 1988 and while some of the chapters cite references as recent as 1990, several have none more recent than 1988 or 1989, suggesting that there has been some delay in publication.

The volume is divided into two sections, the first on the pathophysiology of hypoxia and metabolic acidosis and the second on clinical manifestations of hypoxia. The former section reviews experimental and clinical studies on the effects of hypoxia on the intact circulation and on the normal and compromised heart. This is of current relevance to the increasing interest in the effects of postoperative hypoxaemia on the heart.

The major concern of the second section is lactic acidosis as a consequence of circulatory failure, particularly when it is a result of cardiac arrest, rather than hypoxia *per se*. It will be of interest to those treating such patients, particularly the final three chapters on the treatment of the condition with alkalinizing agents.

This volume will be a welcome addition to the shelves of departmental libraries, despite the relative lack of recent references. It will make a useful starting point for those with an interest in this field and provide a springboard to the current literature.

C. D. Hanning

Moving to Audit, An Educational Package for Hospital Doctors and General Practitioners. C. Arnold, J. Bain, R. A. Brown, R. M. Harden, J. M. Laidlaw, S. McAleer and R. A. Wood. Published (1992) by: The Postgraduate Office, Ninewells Hospital and Medical School, Dundee. Pp. 128; glossary; illustrated. Price: £29.00 (Challenges, Activities, Resource Book and Personalized Feedback); £12.50 (Resource Book only).

The "package" consists of a research manual plus the option to receive "challenges" over the next 6 months. The manual is A4 size and 128 pages of large print entitled "What every doctor needs to know about Medical Audit". The 12 chapters start with definition, work through misconceptions and benefits through to planning. Sampling, measurement and data collection are all discussed, followed by storage, confidentiality and computers. The manual concludes with chapters on data description, interpreting of statistics and keeping audit going. Two sample challenges are included; these establish elaborate "real-life" scenarios to make rather trivial educational points and seem of minor value.

The manual itself is good. It is aimed primarily at general practitioners, but there is much that could be of value to anaesthetists and it is also very suitable for nursing staff and paramedical personnel. It is well presented with clearly marked key messages, questions directed at the reader, follow-up activities and boxed, short case studies. It is easy to read and the references and further reading at the end of each chapter are particularly good.

The basic audit cycle of observation of practice leading to establishment of standards (or a desired performance level), then intervention, followed by re-observation is well known. Many anaesthetic departments are currently embarking on massive data collection exercises as "audit". This book discusses the need for objectives so that the audit produces more than a mass of percentages. Among the important points discussed are co-operation, the need for audit to be non-threatening, that actual benefit must be possible from data collection and what should be studied should be both feasible and affordable. It recommends that small areas be audited. The emphasis is on improving medical care, with only one paragraph mentioning the use of audit for increasing the bargaining power of a group for resources. This seems appropriate; costing exercises are not necessarily audit.

The chapter on questionnaire design is very practical. The statistics sections are designed only to demystify the area so would-be auditors feel happier about reaching for the detailed texts. One area that is not addressed is the role of the professional researcher and statistician. The emphasis of the text is that audit is for everyone! Only once, on page 106, it is rather simplistically suggested: "If you are in any doubt about the statistics to use ask someone who has plenty of experience in sorting out such problems." This is a slight worry. It is one thing for staff to work on improving patient satisfaction with a GP appointments system, but audit procedures which are not always of research quality are now being used to make major professional and financial decisions, and perhaps some caution on this point should have been suggested.

In summary: this is a well written and useful book for those beginning audit procedures.

VOLUME 70, No. 2 FEBRUARY 1993

EDITORIAL I

UPPER AIRWAY REFLEXES

Upper airway reflexes are of great practical importance to anaesthetists. Coughing during anaesthesia may often be only a minor problem, but can occasionally be a serious danger. Aspiration of foreign material into the lungs when pharyngeal coordination and airway reflexes are impaired can cause serious sequelae. Fortunately, although aspiration may be a relatively frequent event after anaesthesia [1], serious complications appear to be rare [2]. Much is known of the components of airway reflexes, but the application of this knowledge to everyday practice is surprisingly patchy. How can we learn more about the impact of anaesthesia on these reflexes?

At first sight, the reflex appears simple. Irritation of receptors in the upper respiratory tract causes a reflex motor response. The receptors of the respiratory tract include slowly adapting ("stretch") receptors responsible for the Hering–Breuer reflex, and rapidly adapting ("irritant") receptors, which are activated briefly by light touch, dust, chemical stimuli and cold air [3]. It is the rapidly adapting receptors that are responsible for the cough reflex. Their afferent impulses run in the vagus nerve, the superior laryngeal branch of which carries afferents from within the upper larynx; the central reflex site is in the medulla, and the efferent impulses are again carried in the vagus to the laryngeal muscles, and by the appropriate nerves to respiratory muscles (diaphragm, intercostal, accessory and abdominal muscles). Some other reflexes involving the larynx are well known by anaesthetists: the "Brewer–Luckhardt" reflex [4] is quoted in old anaesthetic textbooks. This is the response of vocal cord adduction ("laryngeal spasm") that occurs frequently after surgical stimuli such as anal dilatation. However, it is unlikely that any reflex is simple [5]. Further examination of the components of the upper airway reflexes may emphasize this.

Laryngeal afferent neurones with receptive fields in the epiglottis can be activated by a range of stimuli, but mechanical stimuli are most effective, particularly a light touch that moves over several receptive fields [6]. The sensory units consist of free nerve endings that lie between the mucosal cells of the airway epithelium [7]. They can respond faithfully up to high frequencies [8]. More than 50% of laryngeal afferent fibres also respond to cooling or, more exactly, to rate of heat loss from the airway [9]. They also respond to the presence of fluids, particularly water [10], and a variety of chemicals. The response to fluids appears to have a considerable degree of chemical discrimination: isotonic sodium chloride causes very little in the way of stimulation, whereas water, or solutions that are isosmolar but free of chloride ions, are potent stimuli for the laryngeal mucosal receptors [11]. The pattern of nerve firing from epiglottic receptors depends on the nature of the fluid causing the stimulation: low osmolality fluid contact leads to a longer delay and a longer period of activity than a solution that contains no chloride. Similarly, the response after ammonium chloride solution, for example, causes a more high-frequency and rapidly adapting response in a single superior laryngeal nerve fibre than most other substances [12], and it has been suggested that an "afferent portal" in the brainstem decodes these activity patterns before further central projection occurs. Inhalation of isosmolar solutions that lack chloride causes cough; if the solution is not isosmolar, then it causes not only cough, but also bronchoconstriction in susceptible subjects. This latter response is not affected by inhaled lignocaine, suggesting that the mechanisms for these two airway responses are different, despite stimulation of neurally similar receptors [13].

Sensory units appear to be particularly abundant over the arytenoid cartilages and are also found on the laryngeal side of the epiglottis [14]. The superior laryngeal nerve carries a large proportion of small diameter myelinated fibres (group III, A delta or B sensory fibres) [9], which carry afferent impulses from rapidly adapting receptors from structures such as the epiglottis [15].

The recurrent laryngeal nerve also carries sensory fibres [16], mainly from rapidly adapting receptors that are activated by light touch. These receptors are particularly numerous at the anterior and posterior extremities of the inferior surface of the vocal cords. Stimulation of these receptors results in vocal cord movement [17]. Afferent fibres in the laryngeal nerves project centrally to the nucleus tractus solitarius, particularly the caudal and posterior parts [6].

The vagal nerves do not represent the only pathway for airway protective reflexes: for example, potassium chloride applied to the lungs of anaesthetized dogs results in ipsilateral expiratory muscle activity despite section of the vagi, suggesting a spinal reflex via sympathetic afferent nerves [18].

Cough consists of an initial laryngeal opening, followed by a closure of both the glottis and the supraglottic structures; the structures then open and vibrate, and the epiglottis may move forcibly backwards and then forwards again [19].

Laryngeal closure is a complex muscular event, involving activity of muscles that are considered to have abductor effects when active alone. Activation of the laryngeal muscles by stimulation of the internal branch of the superior laryngeal nerve, which causes reflex laryngeal closure, results in a more forceful closure than stimulation of the recurrent laryngeal nerve, which activates the laryngeal muscles directly, but presumably in a less co-ordinated way [20].

Cough does not always follow stimulation of laryngeal receptors, even in susceptible species [21]. In sleeping infants, introduction of small quantities of warm saline into the pharynx, sufficient to cause pooling posterior to the larynx, rarely leads to cough, and more commonly to apnoea and a swallow reflex [22].

The strength of reflex response to laryngeal stimulation appears experimentally to vary with the depth of anaesthesia [23]. The reaction of airways to inhaled substances is reduced by increased mucus secretion, presumably because the mucus protects the airway surface [24]. In contrast, viral infection of the lungs leads to increased airway responsiveness, with amplification of reflex bronchoconstriction involving both afferent and efferent pathways, as discussed by Jacoby and Hirshman [25]. Changes in inspiratory flow rate alter the reaction to inhaled irritant aerosol [26] and may alter the reaction to inhaled ammonia, as discussed by Murphy and coworkers [27].

Using inhaled dilute concentrations of ammonia, Duckett and Hirsh [28] studied 23 patients before surgery, of whom 11 agreed to a repeat study either 24 h after surgery or 24 h after removal of a tracheal tube. Treatment was not allocated randomly and did not appear comparable, but their abstract concluded that tracheal intubation was responsible for a significant reduction in the competence of the glottic reflex.

The motor response to inhalation of a small concentration of ammonia consists of temporary inhibition of inspiration—probably phrenic—and a brief partial adduction of the vocal cords, although inspiratory flow does not cease completely. Greater concentrations can cause coughing. How good a paradigm is this response for the cough reflex?

First, the exact location of the receptors involved is unclear. Although receptors that respond to ammonia have been detected on the epiglottis, and within the larynx, the lower airways are also well supplied with receptors that respond to irritant substances with a rapidly adapting pattern of discharge [29]. Ammonia in concentrations about 100–200 p.p.m. stimulates both continuously active and normally silent laryngeal receptors, but only after a delay of between 2 and 4 s [30]. In lightly anaesthetized patients, insufflation into the nose of a 5% concentration of volatile anaesthetics such as halothane, and particularly enflurane and isoflurane, can cause reflex responses. The duration of expiration increases and the larynx tightens [31].

Thus it is likely that all parts of the airway are involved in the response to inhaled ammonia: the sensation of ammonia inhalation is subjectively localized generally within the larynx and trachea. The sensitivity of the reflex was reduced by local anaesthesia of the airway, but the anaesthesia was extensive, involving injection via the cricothyroid membrane, and thus did not localize any particular receptive field [32].

Second, the stimulus used does not closely resemble a natural stimulus such as foreign material in the airway; finally, the response used as an end-point is not a cough.

Commonly, coughing is caused by entry of foreign material into the larynx and lower airways—that is "something going down the wrong way". The term *laryngeal competence* is often taken to imply, not only an adequate cough response in response to foreign material, but also that the upper airway is sufficiently well co-ordinated to prevent material getting down into the larynx and lower airways in the first place. Impairment of this co-ordination is a frequent accompaniment of recovery from general anaesthesia, and is of particular concern when regurgitation is likely, such as after lower oesophageal resection. The ability to protect the airway returns as central reflex impairment decreases; it is probable that the reflex response to ammonia inhalation does the same. Do interventions such as sedation or general anaesthesia specifically impair airway co-ordination or responsiveness, and the reflex response to inhaled foreign material, more than other reflexes or other indices of central depression such as reaction time? The influences of different anaesthetics appear to vary considerably. For example, the effects of inhaled anaesthetic vapour depend upon the circumstances. A conscious patient can usually breathe 5% halothane vapour without coughing, when requested to do so for the purpose of inhalation induction, but after a "sleep dose" of thiopentone the same patient would cough vigorously if even 1% halothane were inhaled. Since barbiturates do not obviously affect the activity of the airway receptors, it seems that in the conscious state the central reflex is less easily activated. In contrast, the gag reflex is equally vigorous in awake and thiopentone-anaesthetized subjects. Other anaesthetic agents such as propofol have a more depressant effect on upper airway reflexes [33], and animal studies have shown changes in patterns of laryngeal muscle activity with sleep state and barbiturate anaesthesia [34]. The cough reflex is more easily elicited in some species than in others [21].

In consequence of all these factors, it appears unlikely that there will be a constant relationship between tests such as reaction time, and tests of airway reactivity such as ammonia inhalation, when different agents such as barbiturates, benzodiazepines and propofol are investigated, particularly if different species are used. The ideal anaesthetic in this regard would suppress reflex responses such as cough, whatever the stimulus, during anaesthesia and allow rapid recovery after emergence. At first sight, propofol might appear to be valuable, but it appears to have a surprisingly prolonged effect on other respiratory reflexes [35], and it may be that the reflex protection of the airway is similarly impaired for a prolonged period. Indeed, volatile anaesthetics may finally prove to be superior. Cough responses remain, at least at light levels of anaesthesia. During anaesthesia with enflurane (1.5% end-tidal), instillation of small quantities of water into the trachea can evoke reflex responses such as forceful expiration, coughing, panting and apnoea. I.v. lignocaine reduces the panting, coughing and expiratory reflexes, probably by a central action [36]. However, the central actions of different anaesthetics can result in widely different laryngeal responses [37].

Clearly, further study of "laryngeal competence", its components and the effects of anaesthesia and sedation are required. This would be aided by a test of how well a patient can prevent "things going down the wrong way", and of how well things can be coughed out if they do. Ideally this test should not require invasive measurements, patient co-operation or ionizing radiation. The method refined by Langton and his colleagues [38] is a step in the right direction, but it may be necessary to use several paths to reach the goal.

EDITORIAL II

THE LARYNGEAL MASK AIRWAY IN PAEDIATRIC PRACTICE

The laryngeal mask airway (LMA) has become extremely popular worldwide with anaesthetists for control of the airway in a wide variety of circumstances. Although about five times as many adult size LMA are sold as paediatric sizes, their use in children is becoming commonplace.

The LMA was developed after cadaveric studies in the adult [1]. The sizes available for paediatric use are scaled-down versions. The differences in airway anatomy between children, particularly infants, and adults suggest that a scaled-down version may not be as successful for younger subjects. Practical experience led clinical anaesthetists to request an interim size and the manufacturers now produce a size 2.5 for use in children weighing 20–30 kg.

Research into use of the LMA in paediatric practice has focused on the size 2. It was found in three studies that a clinically acceptable airway was obtained in 92–99 % of children weighing more than 6.5 kg [2–4]; this success rate is comparable to that found in studies in adults [5]. The incidence of minor problems on insertion and after removal of the LMA seems to be greater in children compared with adults. Several authors have commented that problems on insertion are often caused by inadequate anaesthesia and Mason and Bingham have recommended the use of an antisialagogue premedication [2].

One clear difference between adult and paediatric use of the LMA is the incidence of an imperfect position diagnosed by fibreoscopy. Rowbottom, Simpson and Grubb [4] reported partial airway obstruction in 19 % of children, compared with an incidence of 10 % in a series in adults reported by Payne [6]. Moreover, the epiglottis could be seen within the mask in 49 % of children in Rowbottom's study. While this does not seem to compromise the airway in the majority of spontaneously breathing children, it may account in part for greater difficulty during positive pressure ventilation, and may interfere with attempts to enter the trachea via the LMA with a tracheal tube or bougie. However, this latter technique has been described in the management of a child with Pierre Robin syndrome [7]. Several authors have reported success in cases of difficult airway caused by a variety of anatomical abnormalities (Pierre Robin [8], Treacher Collins [9], cleft palate [10]). Anaesthetists must remember that where the abnormality resides within the larynx itself, attempts to insert an LMA correctly are likely to fail.

Individuals have developed their own method of insertion [11–14]; however, those who ignore Brain's advice [15] and keep some air in the cuff may increase the chance of downfolding the epiglottis. When difficulty is encountered negotiating the tongue a rotating method, similar to that commonly used to insert a Guedel airway, may often prove useful [12, 13].

The LMA has been advocated for diagnostic laryngobronchoscopy [16, 17]. The vocal cords may be seen with a flexible instrument introduced via the LMA in a spontaneously breathing, anaesthetized patient and this is appealing. However, the fibrescope findings described above caution against use of this technique for diagnostic purposes in children, particularly in laryngomalacia, as the LMA may either distort the epiglottis or not permit inspection.

The LMA has also proved useful during radiotherapy [18], CT scanning and magnetic resonance imaging (MRI). The ability to avoid repeated tracheal intubation during radiotherapy is invaluable. However, Marjot has reported trauma to the pharyngeal wall after repeated use of an LMA [19] and subsequently investigated the pressure exerted. He found that the pressure exerted by the size 2 LMA upon the pharyngeal mucosa would exceed 60 mm Hg unless the inflation volume was much less than recommended [20]. Those who use the LMA for prolonged or repeated use should be aware of the possibility of damage to the pharynx. While this airway is apparently ideal for use during MRI, the metal spring in the valve may distort the image [21] and Fairfield has warned of possible problems during MRI spectroscopy [22]. A reinforced LMA was used successfully in a child who was required to be prone for radiotherapy [23].

The tendency for the original size 2 LMA to kink has been reduced in subsequent versions. However a flexible, reinforced LMA is now commercially available in all sizes except size 1. This new product is recommended for use in head, neck and dental surgery, including tonsillectomy. The manufacturers warn of greater resistance to breathing caused by smaller internal diameter (i.d.) and greater length. The reinforced size 2 LMA has a tube with an i.d. of 5.1 mm, compared with 7.0 mm for the ordinary LMA tube. Bhatt and colleagues have found that the non-reinforced LMA (all sizes) imposes less resistance and requires lower additional inspiratory work compared with the corresponding sized tracheal tube [24]. A similar study is required for the reinforced LMA.

Anaesthetists who are tempted to use the reinforced LMA when subsequent access to the airway is restricted must ensure that adequate airway monitoring is undertaken and that the surgeon is fully aware that any movement of the head, neck or drapes, insertion of a pack etc. that would be acceptable with a tracheal tube in place, may displace the LMA. As with the introduction of the LMA, clinical experience and controlled study should establish the place of the reinforced LMA, especially for intra-oral and pharyngeal surgery.

Published research to date has not studied the size 1 LMA in large numbers, but those who have examined this type urge caution in its use [25]. Relatively few are sold and this reflects a reluctance to use the device in small infants. The anatomical differences between infants and children imply that a satisfactory position is more difficult to achieve in infants. Thus positive pressure ventilation is less successful and, in particular, inflation of the stomach may be more likely.

The writer shares the concern of others [26–28] that increasing dependency on the LMA by trainee anaesthetists will result in a lack of experience and skill in managing with a face mask an awkward or obstructed airway in unconscious patients. The management of cases such as acute epiglottitis without this skill is impossible.

The LMA undoubtedly has become well established in paediatric practice. There is insufficient published work on IPPV or the use of the size 1 to advocate widespread use. The use of the LMA in children should remain the province of the experienced anaesthetist, who should ensure that more junior anaesthetists first gain experience in conventional airway management in children.

MEASUREMENT OF THE SENSITIVITY OF UPPER AIRWAY REFLEXES

J. A. LANGTON, P. J. MURPHY, P. BARKER, A. KEY AND G. SMITH

SUMMARY

We describe a method for measurement of the sensitivity of upper airway reflexes. The technique is based upon delivery of an irritant chemical stimulus (dilute concentrations of ammonia vapour) to the upper airway. The technique is non-invasive and uses equipment which is portable, allowing measurements to be made in the clinical environment. (Br. J. Anaesth. 1993; **70**: 126–130)

KEY WORDS

Airway. Measurement techniques: airway reflexes.

During induction of anaesthesia, heightened upper airway reflexes may lead to laryngospasm and airway obstruction, and during recovery from anaesthesia, rapid return of laryngeal and upper airway reflexes is important to protect the lower airway from aspiration. Laryngeal competence may be reduced after tracheal intubation [1–4] and may contribute to atelectasis and respiratory failure [2], especially in the elderly.

In early work, Hoglund and Michaelsson [5] attempted to measure the reactivity of the upper airway using small concentrations of ammonia vapour; 10 years later, Pontoppidan and Beecher [6] used a similar technique, but in both these studies, the concentration of ammonia vapour inhaled by the subject was not known accurately, and their results were variable and unreliable.

The aim of our study was to develop a method which would measure the sensitivity of upper airway reflexes reliably. We have modified a previously described method, and designed new portable equipment that allows measurements to be made in the clinical environment. The reliability of this technique was evaluated in normal volunteers.

SUBJECTS AND METHODS

Measurement system

Small concentrations of ammonia vapour were used as an irritant chemical stimulus. The subject's upper airway was exposed to single intermittent breaths containing a small concentration of ammonia and, by measurement of the inspiratory flow pattern, a measure of the sensitivity of the subject's upper airway reflexes was made. This was expressed as the threshold concentration, that is the smallest concentration of ammonia required to elicit a reflex response.

The system is shown diagrammatically in figure 1. A small concentration of ammonia vapour in air was produced in the ammonia limb of the breathing system by mixing air from an air pump flowing at 10 litre min^{-1} with an adjustable flow of ammonia in nitrogen. The ammonia was delivered via a flowmeter from a calibrated cylinder containing 3% ammonia in nitrogen. The breathing system was calibrated to deliver accurate concentrations of ammonia vapour in the range 0–3500 p.p.m. The gas mixture flowed via a reservoir bag and clear plastic tubing around the system, as indicated in the figure by the arrows.

A pneumatic two-way balloon valve (V) allowed the subject to breathe room air via limb B: on switching the pneumatic valve, the subject took a single breath from the ammonia in air limb A. The two-way pneumatic balloon valve (Hans Rudolph) was controlled by the investigator and allowed the mixture to be directed to the subject for *one breath*, or to pass around the system to a specially constructed absorber without the subject being aware of the change. The balloon valve had a low compliance and an inflation time of 45–60 ms and deflation time of 60–75 ms.

The switching device, pneumotachograph head and mouthpiece were supported by an adjustable arm and held at a height convenient to the subject's mouth with the subject in either the sitting or the supine position. A Gould pneumotachograph recorded inspiratory flow pattern onto a Gould 2022 chart recorder. The subject breathed through a close fitting mouthpiece, whilst wearing a noseclip, via one-way valves, and exhaled to atmosphere. Subjects wore dark goggles and listened to music via a pair of headphones so that they were unaware of the switching of the pneumatic valve.

The absorber contained crystals of sodium benzoate absorbed onto silica gel matrix. Ammonia

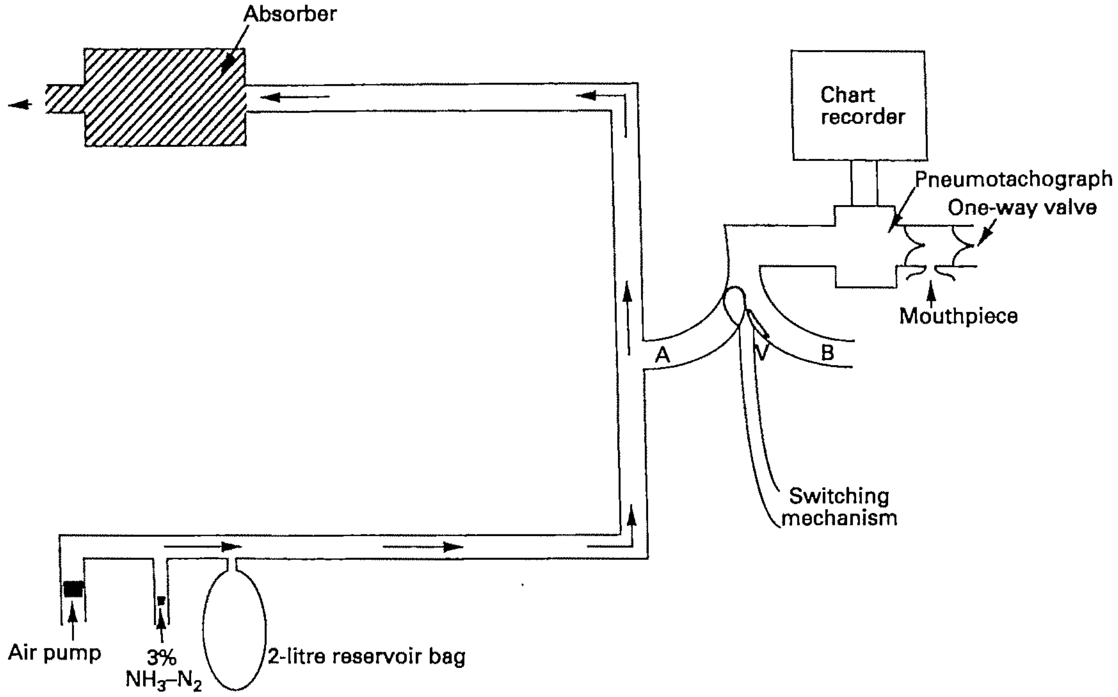

FIG. 1. Diagram of the equipment used to measure the sensitivity of upper airway reflexes. A = Ammonia–air limb; B = room air limb; V = balloon valve.

TABLE I. *Calibration data (mean († SEM; ‡ SD))*

Flowmeter setting	Measured flow (ml min^{-1})	Final [NH$_3$] (p.p.m.)	Time to 95% final [NH$_3$] (s)
50	73.1 (9.1)†	76 (12.3)‡	105
100	155.1 (1.02)	251 (12.6)	105
200	195.6 (0.85)	524 (33.7)	70
300	241.3 (0.54)	878 (17.8)	70
400	332.8 (0.88)	1140 (18.8)	70
500	427.1 (0.2)	1620 (61.5)	70
600	539.5 (2.95)	1970 (52.1)	70
700	635.5 (1.35)	2360 (60.4)	70
800	749.3 (0.63)	2790 (56.6)	70
900	863.7 (0.83)	3160 (142.2)	70
1000	964.6 (3.11)	3550 (170.2)	70

vapour in the carrier gas was removed by reaction with the crystals to produce ammonium benzoate and water. The crystals contained a marker dye which changed colour when the crystals were exhausted.

Calibration

Air. The air flow through the oxygen flowmeter was calibrated using a dry gas meter. With the flowmeter set at 10 litre min^{-1}, the total measured flow over a 30-min period was 324.9 litre (10.83 litre min^{-1}).

Ammonia–nitrogen. The flow of the 3% ammonia–nitrogen mixture via the cyclopropane flowmeter was measured using a bubble flowmeter (table I). The final ammonia concentration (p.p.m.), and the time (s) required for the concentration of ammonia to reach 95% of the final concentration were also recorded (table I). The concentration of ammonia produced in the system varied in the range 76–3550 p.p.m. at the differing flow rates. The time required to achieve 95% of the final concentration was 105 s at the slower flow meter settings of 50 and 100 ml; at faster flows, the time to reach 95% of the final concentration was 70 s.

The time for the ammonia concentration to decrease to zero after the ammonia–nitrogen flow was stopped was less than 2 min at all flow rates.

Ammonia–air. Small concentrations of ammonia in air were measured using a Bruel and Kjaer multigas analyser type 1302. The measurement principle used in this gas analyser is based on the photo acoustic infra-red detection method. The selectivity of the multigas analyser is determined by the optical filters installed. By studying the absorption spectra of gases to be monitored, the relevant optical filter is installed and the analyser zero calibrated and then span calibrated using the known certified ammonia concentration.

The Bruel and Kjaer multigas analyser was calibrated by the manufacturers to measure ammonia to a concentration of 10 p.p.m. (0.001%). The filter used was type 0976 with a centre wavelength 10.6 µm.

Initially, zero readings were obtained using a gas known not to contain ammonia vapour. The multigas analyser was then span calibrated using the certified gas concentration of 3.12% ammonia–nitrogen supplied by the British Oxygen Company. The breathing system was then calibrated in several stages. Measurements of the concentration of ammonia–air were made in the ammonia–air limb opposite the pneumatic switching valve (V).

The time to produce a reading and the concentration of ammonia in the circuit were measured. The air flow was set at 10 litre min^{-1}, the ammonia–nitrogen flow was started at 50 ml min^{-1} and recordings of ammonia concentration were started. Ten measurements were made over a period of 3–4 min. Then the ammonia–nitrogen flow was stopped and the time for the reading to decrease to zero was noted.

The calibration was performed at flows of ammonia–nitrogen 50 and 100 ml min^{-1} and then at increasing flow rates of ammonia–nitrogen in 100-ml increments up to a maximum of 1000 ml min^{-1}.

Volunteer studies

After obtaining Ethics Committee approval and informed written consent, we studied 10 healthy, non-smoking volunteers (eight male; ages 29–35 yr, weights 72–85 kg). The subjects were not taking any medication, were asked to refrain from drinking alcohol from noon the previous day, and were starved for 6 h before the study. We excluded subjects who were known asthmatics, and volunteers who were suffering from, or had a history of an upper respiratory tract infection within the previous 1 month.

Measurements of upper airway reactivity were made using the system described above.

The subject rested on a couch, wearing blackened goggles and listened to continuous loud music via a pair of headphones. A noseclip was applied and the subject was allowed to breathe through the mouthpiece via the one-way valve. The pneumatic switching valve was operated by the investigator at the end of expiration, so that the subject took one inspiratory breath from the ammonia limb.

The concentration of ammonia–air was increased in a stepwise manner in the ammonia limb (A), starting at the smallest concentration of ammonia. The threshold level of response to the ammonia stimulus was determined by the occurrence of a glottic stop, defined as a rapid decrease in the inspiratory flow, the flow decreasing by at least 25% of the peak inspiratory flow, followed by a swift recovery, the whole event lasting less than 0.5 s. An example of a glottic stop is shown in figure 2.

Each subject was investigated every 30 min for 4 h, and on six different days at least 1 week apart, in order to determine the reliability and repeatability of our measurements. In some subjects, we also presented the ammonia concentrations in a random order.

The deadspace of the equipment was calculated by measuring the volume of water required to fill it (48 ml).

RESULTS

Volunteers

The concentrations of ammonia vapour required to produce a glottic stop in each of the 10 volunteers are shown in table II.

The mean threshold of sensitivity of the upper airway was in the range of concentrations of ammonia 363–642 p.p.m. Statistical analysis (Mann–Whitney-*U* test) showed no significant differences between the measurements made repeatedly on one day compared with measurements made on separate days.

TABLE II. *Threshold concentration of ammonia required to cause a glottic stop in 10 subjects (mean (median) [interquartile range])*

Subject	Threshold concn (p.p.m.) Different days ($n = 6$)	Same day ($n = 8$)
A	642 (524) [524–878]	465 (524) [376–524]
B	642 (524) [524–878]	499 (524) [524–674]
C	387 (387) [251–524]	363 (289) [251–524]
D	380 (387) [251–524]	471 (524) [327–524]
E	504 (524) [455–600]	435 (425) [327–524]
F	537 (524) [455–612]	544 (524) [524–674]
G	573 (524) [524–870]	440 (327) [327–524]
H	495 (524) [524–674]	536 (524) [524–600]
I	549 (524) [524–600]	536 (524) [524–543]
J	596 (524) [524–699]	627 (524) [524–678]

We found that, when the ammonia stimulus was presented in a random order rather than in an ascending challenge, the thresholds were the same, but the subjects found this to be considerably more unpleasant. Therefore this was performed in only five subjects.

DISCUSSION

Laryngeal reflexes are evoked by chemical or mechanical stimuli via receptors thought to be located in the hypopharynx and larynx [7]. Afferent pathways travel in both the parasympathetic and sympathetic nervous system and the motor response is temporary closure of the vocal cords [8]. In 1870, Kratschmer [9] demonstrated that mechanical and chemical irritation of the laryngeal and nasal mucosa caused reflex glottic closure and this reflex is now termed the Kratschmer reflex.

Hoglund and Michaelsson [5] described a technique for eliciting the Kratschmer reflex in humans. This involved injecting dilute ammonia vapour into the subject's breathing system using multiple gas syringes, each filled with a different concentration of ammonia vapour. This chemical stimulus produced temporary closure of the glottis and inhibition of inspiration, sensed by a pneumograph around the subject's waist. The concentration of ammonia required to produce this reflex was 800–1600 p.p.m. Pontoppidan and Beecher [6] investigated the effects of ageing on laryngeal reflexes, using a similar method. Ventilation was monitored with a wet spirometer, but their system contained a considerable deadspace (approximately 300 ml). The results indicated a decrease in protective laryngeal reflexes with increasing age. In 1971, Hinkle and Tantum [7] used a multiple syringe technique with a large deadspace to investigate the effects of codeine phosphate on laryngeal reflexes, and in 1980 Duckett and Hirsh [10] investigated glottic competence in a small number of postoperative patients, and found increased thresholds in all patients who had undergone tracheal intubation.

In 1987, Groves, Rees and Rosen [11] studied the effect of i.v. Diazemuls and lormetazepam on laryngeal reflexes in volunteers. After Diazemuls 15 mg i.v., the ammonia thresholds were increased by 200% and remained increased for more than 4 h.

All of the studies described above suffered from several problems leading to inaccuracy. The final concentration of ammonia reaching the subject's larynx was not known accurately because of large deadspaces [6]. It may also have been affected by streaming or channelling of gas flow through the breathing system; the subjects may therefore have had warning of the imminent arrival of ammonia because the gas was not presented as a bolus. An early prototype of our equipment contained a large deadspace (300 ml), and that was associated with large scatter of results in individual subjects who volunteered that they could sense that the next breath contained ammonia. In further development of our equipment, we have reduced the deadspace volume to 48 ml, with marked improvement in the reproducibility of the results obtained.

The use of pre-prepared syringes and lack of an absorber in these early methods also made them unsuitable for use in the clinical environment.

The mechanism of the glottic stop is not known. Inhalation of irritant vapour stimulates chemoreceptors and rapidly adapting irritant receptors thought to be located in and around the entrance to the larynx. In work by Szereda-Przestaszewska and Widdicombe in cats [12], it was found that the response to insufflation of ammonia vapour across the larynx was virtually abolished by sectioning the superior laryngeal nerve. This provides some evidence for an upper airway site for the afferent limb of this reflex. In earlier work, Widdicombe [13] had observed that mechanical or chemical irritation of the laryngeal mucosa caused laryngeal adduction, even if the stimulus was too weak to cause coughing. It is thought that chemical irritation of the upper airway causes rapid movement of the vocal cords across the inspiratory air flow [7], with interruption to inspiration. With greater inhaled concentrations of irritant vapour, a cough is elicited. A repeatable observation in our subjects was that the glottic stop response occurred at concentrations of ammonia vapour smaller than those required to elicit a cough response.

Previous workers [7], using x-rays to image the movements of the vocal cords, demonstrated that the vocal cords adduct across the inspiratory air flow during a glottic stop, and concluded that this adduction of the vocal cords was the cause of the decrease in the inspiratory air flow. Several of our volunteers spontaneously reported a feeling of sudden involuntary closure in the throat when a glottic stop occurred. Using an ultrasound technique to image the vocal cords [14], we have recorded the movements of the vocal cords during a glottic stop: the cords were seen to adduct rapidly and then abduct, coinciding with the appearance of a glottic stop on the inspiratory flow trace.

In summary, we have described a method of measuring the threshold response of the upper airway to an ammonia stimulus. The subjects found that the technique was acceptable and not unpleasant. Measurements in young, non-smoking volunteers showed a mean threshold of response at ammonia 363–642 p.p.m. There were no significant differences in the mean threshold values recorded on the same day or on separate days.

ACKNOWLEDGEMENTS

We thank Bruel & Kjaer Ltd for the loan of the Multigas analyser. We are also grateful to the Trent Regional Health Authority for a research grant to support the cost of undertaking these studies and to the Association of Anaesthetists of Great Britain and Ireland for an equipment grant.

EFFECT OF ORAL DIAZEPAM ON THE SENSITIVITY OF UPPER AIRWAY REFLEXES†

P. J. MURPHY, J. A. LANGTON, P. BARKER AND G. SMITH

SUMMARY

In a double-blind, cross-over study, we have investigated the effect of oral diazepam 20 mg and placebo on the sensitivity of upper airway reflexes in 10 male volunteers (aged 25–35 yr). Upper airway reflex sensitivity (UARS) was assessed using small concentrations of ammonia vapour as a stimulus to upper airway receptors. A threshold concentration of ammonia, at which reflex glottic closure occurred in response to the ammonia stimulus, was used as a measure of UARS. With diazepam, there was significant depression of UARS from 30 to 150 min after administration. (Br. J. Anaesth. 1993; **70**: 131–134)

KEY WORDS

Hypnotics, benzodiazepines: diazepam. Measurement techniques: airway reflexes.

Receptors known to respond to chemical irritants are found in the epithelial and sub-epithelial layers of the larynx and pharynx [1]. Afferents from these fibres travel mainly in the superior laryngeal nerve and synapse in the brain stem. In adult humans, the main responses to irritant receptor stimulation are glottic closure and a brief stop in inspiration [2]. At higher levels of stimulation the reflex response produced is termed the expiration reflex or laryngeal cough (a short expiratory effort without preceding inspiration) [3].

Upper airway reflex activity is important, with implications for both airway protection and upper airway complications during anaesthesia (laryngospasm, coughing). Previous work has shown that subjects given Diazemuls 15 mg i.v. had a 200% decrease in the sensitivity of upper airway reflexes, which persisted for at least 4 h after administration of the drug [4]. The apparent longevity of this reflex depression compared with the short-lived clinical effects of a single dose of i.v. Diazemuls has major implications, as it suggests that a patient may be at increased risk of aspiration despite appearing recovered from acute sedative effects. The aims of this study were to assess the effect of a premedicant dose of oral diazepam on upper airway reflexes and to investigate the time course of this effect.

SUBJECTS AND METHODS

In a double-blind, cross-over study, we have investigated 10 healthy, non-smoking, male volunteers (aged 25–35 yr) who were currently taking no medications. The subjects abstained from alcohol from noon the previous day and had a light breakfast on the day of the study. Exclusions included any subject developing an upper respiratory tract infection within 1 month before or during the study and those with a history of atopy.

Subjects were allocated randomly to receive diazepam 20 mg orally on one occasion, and placebo on another. The investigators and subjects were blinded to the identity of the medication by a system of coded envelopes (the code being broken only at the end of the study).

Baseline measurements of upper airway reflex sensitivity (UARS) and reaction time to an auditory stimulus (ART) were measured, after which subjects ingested the medication. Subsequently, measurements of UARS and ART were made every 30 min for the next 4 h.

At least 1 week later this procedure was repeated, the subject taking the alternative medication.

All subjects were advised not to work or drive a motor vehicle for 24 h after each medication.

Assessment of UARS using small concentrations of ammonia vapour as a chemical stimulus has been described [5–7]. We have recently modified the original technique to produce a more reliable system [8]. UARS was assessed with this new system, as described in the accompanying paper [9].

ART was measured using an electronic timer. We recorded the time taken for the subject to press a trigger in response to an auditory stimulus (bleep) administered via headphones. The bleeps occurred at random intervals. At the end of each 30-min interval, 10 recordings of auditory reaction time were taken and the mean value recorded. Each subject was allowed ample practice time before commencing the study, in order to eliminate practice effects.

Data were analysed using multiple analysis of variance and paired t tests; significance was taken at $P = 0.05$.

After diazepam, paired ART and ammonia threshold values, for each individual at each time-point,

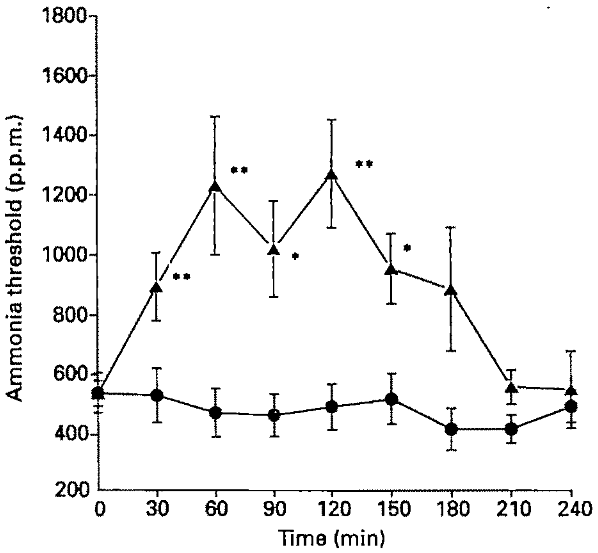

FIG. 1. Relationship between ammonia threshold (mean, SEM) and time. ▲ = Oral diazepam; ● = placebo. $*P < 0.05$; $**P < 0.01$ between groups.

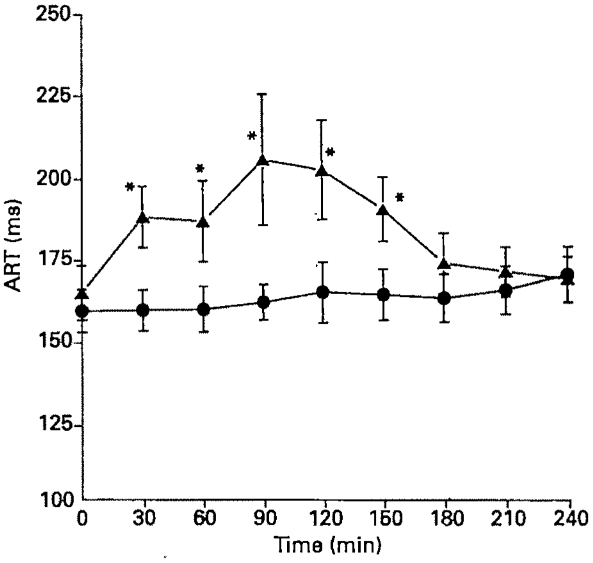

FIG. 2. Relationship between auditory reaction time (ART) (mean, SEM) and time. ▲ = Oral diazepam; ● = placebo. $*P < 0.05$ between groups.

were plotted against each other. Correlation of these variables was tested using the Spearman Rank Correlation Coefficient.

RESULTS

All 10 subjects successfully completed the study. After oral diazepam 20 mg, mean ammonia threshold values increased from a baseline of 538 p.p.m. to a peak of 1266 p.p.m. at 120 min and had decreased to 537 p.p.m. by 240 min. Significant increases in the ammonia threshold concentrations occurred between 30 and 150 min. After placebo there was no significant change in ammonia threshold (fig. 1).

After diazepam, mean ART increased from a baseline of 165 ms to a peak of 205 ms at 90 min and had decreased to 167 ms by 240 min. After placebo, there was no significant change in ART (fig. 2).

Correlation testing of paired ART and ammonia threshold values following diazepam gave an RS value of < 0.2.

DISCUSSION

Ammonia vapour stimulates sensitive nerve endings situated in the laryngeal epithelium and some laryngeal pressure receptors [10]. At a threshold of stimulation, a reflex response occurs which results in glottic closure and a brief pause in inspiration. We have used this ammonia threshold as a measure of upper airway reflex sensitivity.

Simple auditory reaction times have been used before to assess recovery after diazepam [11]. In this study we used ART as a measure of sedation in order to identify the time course of the major sedative effect of oral diazepam.

We have found that, after oral diazepam 20 mg, significant depression of UARS occurred between 30 and 150 min, but within 210 min UARS had returned to baseline values. This change followed a similar time course as changes in ART. However, after diazepam, there was no correlation between individual ART and ammonia threshold values. This lack of correlation may be attributable to several factors. For example, in many individuals the peak effect on ART occurred earlier or later than the peak effect on ammonia threshold. Also, some subjects exhibiting a marked increase in ammonia threshold had only small changes in ART, raising the possibility that measurement of ART may itself lead to increased arousal and in some individuals produce falsely decreased ART values.

After placebo there was no significant change in UARS. These data suggest that there appeared to be little tachyphylaxis to the ammonia stimulus during the period of the study.

The timing of the changes in UARS is explained easily in relation to the pharmacokinetics of oral diazepam. Studies have shown that the mean plasma first-phase half-life of a single oral dose is 5.08 h [12], with the peak effect occurring at 60 min [13, 14]. Although we cannot compare our study directly with one in which i.v. Diazemuls was used, there does appear to be a discrepancy between our results and those of the previous study [4] which demonstrated prolonged depression of UARS with maximal reflex suppression still present at 4 h after Diazemuls 15 mg i.v. Pharmacokinetic data for a single dose of i.v . Diazemuls indicate peak plasma concentrations are achieved within minutes, followed by a rapid decrease in plasma concentrations as redistribution of the drug takes place [13]. Thus one would expect i.v. Diazemuls to have a more transient effect than a similar dose of oral diazepam. This is supported by previous work which suggests that laryngeal competence is impaired for only 5–15 min after i.v. Diazemuls [15].

The answer to this discrepancy may lie in part in the improvement of UARS measurement provided by our new technique. Early work in our department, using a prototype, showed that a large deadspace between the mouthpiece and the switching mechanism resulted in poor reproducibility and an increase in intra-individual variability of UARS measurement. It would appear that a large deadspace alters the presentation of the ammonia stimulus to the laryngeal receptors, presumably by allowing greater mixing of the ammonia stimulus with deadspace gas, such that the rate of increase in the ammonia concentration at the receptor is reduced. As the receptors which respond to the ammonia stimulus are thought to be rapidly adapting [10], it is possible that such changes may result in altered receptor activity. In the previous study, workers used a system with an apparent deadspace of 200 ml. The deadspace in our new system is 48 ml [8].

There was considerable increase in intersubject variability of ammonia threshold values after oral diazepam. It is well known that there is some inter-individual variability in the time taken to reach peak diazepam plasma concentrations after an oral dose. After oral diazepam 0.3 mg kg^{-1}, peak plasma concentrations have been shown to occur within 1 h in more than 80 % of subjects and to have decreased to 30–60 % of maximum values within 6 h in most subjects. However, in some individuals peak plasma concentrations may not occur until 6 h after an oral dose [12].

It is possible also that some of the variability may be secondary to changes in inspiratory flow after diazepam. Studies using citric acid aerosols to induce cough found that slower inspiratory flows were associated with a greater cough stimulus, probably because of increased laryngeal deposition [16]. Although a stimulus technique using ammonia vapour differs from one using a citric acid aerosol, it is possible that changes in inspiratory flow may affect the rate of change of the ammonia stimulus at the laryngeal receptors. Although we used recordings from the pneumotachograph to identify glottic stops, we did not measure inspiratory flow rates accurately. However, previous work has shown that diazepam 0.15 mg kg^{-1} i.v. appears to cause slight, but not significant, depression of mean inspiratory flow rates [17]. It is unlikely, therefore, that any changes in inspiratory flow after oral diazepam would have had a major effect on our measurement of UARS, but they may have added to the variability.

Because the larynx also contains cold receptors and some chemosensitive nerve endings which may not be stimulated by ammonia [10], we cannot be certain that all reflexes evoked by stimulation of laryngeal receptors are depressed to the same extent by diazepam. However, the irritant receptors which respond to ammonia also respond to ether [2] and are most probably implicated in laryngeal reflexes induced by other anaesthetic agents.

The laryngeal closure reflex is thought to be a brainstem reflex and many factors [18], including central inhibitory influences [19], have been shown to affect it. It is probable that diazepam produces suppression of upper airway reflexes by facilitating inhibitory neurotransmitter activity, although it is not clear if this occurs via general depression of CNS activity or via more specific inhibitory pathways.

We conclude that oral diazepam 20 mg resulted in a significant reduction in the sensitivity of upper airway reflexes, as measured by our technique, from 30 to 150 min in healthy young men. This implies that, to depress upper airway reflexes and thus reduce airway complications during induction of anaesthesia, oral diazepam should be administered in the period from 30 min to 2 h before induction. As previous work has shown that upper airway reflex sensitivity decreases with age [20], special care should be taken when using this drug with elderly patients as further depression of upper airway reflexes may be undesirable.

LOGISTIC REGRESSION ANALYSIS OF FIXED PATIENT FACTORS FOR POSTOPERATIVE SICKNESS: A MODEL FOR RISK ASSESSMENT

M. PALAZZO AND R. EVANS

SUMMARY

One hundred and forty-seven patients undergoing minor orthopaedic surgery were studied prospectively by logistic regression analysis to determine the association of independent fixed patient factors with the incidence of postoperative sickness (nausea, retching or vomiting). Gender, history of previous postoperative sicknness, postoperative opioids and interaction between gender and previous history of sickness were significant independent factors for postoperative sickness; history of motion sickness was weakly associated. The probability of postoperative sickness in the first 24 h after surgery may be estimated from the equation: logit postoperative sickness = $-5.03+2.24$*(postoperative opioids)*$+3.97$*(previous sickness history)*$+2.4$*(gender)*$+0.78$ *(motion sickness)*-3.2*(gender × previous sickness history). (Log likelihood ratio test for 5 degrees of freedom for the coefficients, chi-square = 53.5 (*$P < 0.001$*).) It is suggested that the calculated probability for sickness may be a useful addition for balancing patient treatment groups and allowing between-study comparisons.* (Br. J. Anaesth. 1993; **70**: 135–140)

KEY WORDS
Vomiting: nausea, postoperative, preoperative factors. Risk.

Postoperative sickness (nausea, retching and vomiting) occurs frequently after anaesthesia and surgery. Clinical impressions of a decrease in the incidence and severity of sickness are not supported by evidence published over the past 35 years [1–9] (table I). This may reflect, in part, variability in the method of investigation. There are many alleged causes of postoperative sickness, some patient-related, others technique-related [10, 11]; these factors make adequately controlled clinical trials difficult to conduct. Although most studies control technique factors they usually fail to establish strictly matched patient groups. There may therefore be a need to establish some well-defined criteria by which patients can be considered comparable, particularly for the evaluation of antiemetics. The purpose of this preliminary study was to see if it is possible to provide a basis upon which to define comparable patients.

PATIENTS AND METHODS

Study design

The factors that may influence postoperative sickness may be classified into those related to the patient and those related to anaesthetic technique or management. Patient or technique factors may be classified further as "fixed" or "variable" factors. Fixed factors are those which cannot be altered, such as gender or previous history of sickness. Variable factors are those which may be modified by the anaesthetist. Most patient factors are fixed. In contrast, technique factors may be fixed, or may be allowed to vary depending on experimental design. The primary aim of this study was to isolate and quantify the relative effect of fixed patient factors on the incidence of postoperative sickness. An important aspect of the design of this study, therefore, was to ensure strict control of all possible technique factors while allowing the fixed patient factors to distribute freely without experimental bias among those who vomit and those who do not. Additionally, an attempt was made to reduce the confounding effect of controlled technique factors on the incidence of sickness by using the least emetic anaesthetic technique available. It was hoped that this would highlight the contribution of the fixed factors to postoperative sickness.

The study design and analysis assumed that fixed patient factors did not have equal influences on the incidence of postoperative sickness and, furthermore, that they may have interacted to introduce additional independent variables. For this reason, statistical analysis of individual factor effects was assessed by logistic regression.

Patients

We studied 147 ASA I adult patients (80 female) undergoing minor peripheral orthopaedic surgery,

TABLE II. *Some of the factors that may be associated with postoperative sickness. These can be classified into factors associated with the patient or those associated with technique. Most patient factors are fixed. Variable factors, either patient or technique may be fixed by study design*

Factors examined	Factors controlled
Age	Preoperative assessment
Weight	Premedication
Sex	Induction agent
Duration of preoperative fast	Maintenance agents
Previous postoperative emetic history	Oropharyngeal suction
History of motion sickness	Guedel airway
History of sickness with pregnancy	Mask ventilation
Heartburn	I.v. fluids
History of sickness with pain	Journey to theatre from ward
History of sickness with alcohol	Journey from theatre to recovery
Anxiety before induction	Recovery position
Nausea before induction	Duration of postoperative observation
Thirst before induction	Nurses observing patients
Hunger before induction	Anaesthetist
Duration of anaesthesia	Time of first ambulation
Opioid administration	Time to first oral intake

presenting sequentially over a 3-year period. Patients who were pregnant or lactating were not included. Hospital Ethics Committee approval and patient agreement to the study were obtained before the study. In order not to alert patients to our special interest in postoperative sickness, their consent was sought for the investigation of a variety of postoperative complications.

All patients were admitted to the same ward the evening before surgery. Each patient was interviewed by one of the investigators as part of the routine preoperative assessment. A standard questionnaire was used to determine the fixed factors from the patient's history. Questions were distributed equally between those which were thought relevant to postoperative sickness and those which were not; the questions were asked in random order, to minimize bias.

Patients were allocated randomly to receive either a light meal or no meal 6 h before anaesthesia. All patients received oral premedication with diazepam 10 mg 90 min before anaesthesia. Patients, lying supine, were taken by trolley from the ward to the anaesthetic room, so that all experienced the same journey.

In the anaesthetic room, the patients were asked additional questions which sought information on whether or not the patient was hungry, thirsty, sleepy, anxious or feeling sick before induction of anaesthesia.

Anaesthesia was induced with thiopentone 4 mg kg^{-1}, followed by oxygen 3 litre min^{-1}, nitrous oxide 6 litre min^{-1} and increasing concentrations of enflurane via a Bain system. Care was taken to avoid apnoea, thus obviating the need for ventilatory assistance by mask. During induction, insertion of a Guedel airway and oropharyngeal suction were avoided. Patients who had ventilatory assistance, suction or insertion of an oropharyngeal airway at any time during the anaesthetic management were excluded from the analysis. No patient received supplementary local or regional anaesthesia.

Anaesthesia was maintained by spontaneous ventilation of a mixture of 2% enflurane and 65% nitrous oxide in oxygen via a face mask and Bain system. Patients were monitored with non-invasive arterial pressure measurements, pulse oximetry and ECG.

All patients received an i.v. infusion of Hartmann's solution during anaesthesia. The volume administered was calculated to compensate for the period of fasting and included any additional loss during surgery. The infusion was completed before the end of surgery. The volume for the fasting period was calculated as 1.5 ml kg^{-1} h—for example, a 70-kg patient who had fasted for 7 h received 735 ml.

At the end of anaesthesia, a standard routine was followed for each patient. All patients were placed in the left lateral position, received supplementary oxygen therapy and were sent to a 24-h recovery room with attention paid to the airway, avoiding oropharyngeal suction or insertion of a Guedel airway. If there was a need for additional airway intervention at this stage, the patient was withdrawn from the study. A total of 11 patients were excluded, for reasons of loss of postoperative data (six patients), variation from the study design (four patients) and inadvertent inclusion of one patient twice.

Patients were allowed papaveretum, paracetamol and antiemetics as required. Consequently, postoperative opioid analgesia was considered a fixed factor for the purposes of this study and was not controlled. The total dose of analgesics administered was recorded over 24 h. All episodes of postoperative sickness were recorded for 24 h. Postoperative sickness was defined as vomiting (an integrated reflex which results in forceful expulsion of stomach contents), retching (a non-productive vomit) and nausea (the sensation of wishing to vomit or retch). No attempt was made to grade the severity of postoperative sickness. A "vomiter" was any patient who had at least one episode of nausea, retching or vomiting. Episodes of nausea, retching and vomiting were either volunteered, witnessed or elicited as the result of direct questioning by the nursing staff. Concomitant changes in heart rate, arterial pressure and ventilatory frequency were recorded with any obvious provocative episodes such as early ambulation. Oral fluids were not given until 4 h after anaesthesia, but were freely available thereafter. The same nurses observed all the patients (maximum four patients cared for by one recovery nurse) throughout the study. These nurses were aware of a study on postoperative complications but were not aware of its design or of the patients' responses to previous questioning. Table II shows a list of all the factors that were examined.

Statistical analysis

The data obtained from this study were either categorical, such as patient gender, or continuous, such as age, weight and duration of anaesthetic. The anaesthetic technique factors were strictly controlled, leaving the patient factors to distribute freely.

All the continuous data were examined by Mann–Whitney *U* test between vomiters and non-vomiters. Significant statistical differences were assumed at $P < 0.05$. All the categorical data that were not controlled by study design (fixed patient factors) were also examined initially by a univariate method (2×2 contingency tables) between vomiters and non-vomiters for rapid identification of possible important differences. The uncontrolled categorical data (fixed patient factors) and continuous data (age, weight, duration of fast and duration of operation) were examined by logistic regression (logit module, Systat 5.1 for the Macintosh, Systat, Illinois, U.S.A.). Logistic regression makes no assumption about distribution.

The independent factors were indicated as 1 if present and 0 if absent (for gender 1 was female and 0 male). The inclusion of factors was determined by a forward stepwise regression of the main factors, followed by interactions. The threshold for inclusion of a factor was a probability of 0.15 or less based on log likelihood test ratio $G(G = -2$ (log likelihood test ratio for the model without the additional factor) – (log likelihood test ratio for the model with the additional factor)) [12].

Maximum likelihood estimators (coefficients) were calculated for each factor from which odds ratios were determined. The odds ratios were expressed as probabilities for postoperative sickness. The probabilities of postoperative sickness for baseline and various factor combinations were calculated with their 95% confidence limits [12, 13].

Examples of these calculations are shown in the Appendix.

RESULTS

The uncontrolled factors (continuous and categorical) examined are listed in table II. The continuous variables, age, weight, duration of operation and duration of fast were distributed evenly between vomiters and non-vomiters (table III). These factors also failed to reach the inclusion criteria for the logistic regression model. Their coefficients were less than 0.01 and log likelihood test ratios gave *P* values between 0.4 and 0.6.

The uncontrolled categorical factors (fixed patient factors) were also analysed initially by 2×2 contingency tables between vomiters and non-vomiters (table IV). Among these factors, only four appeared to have any association with the incidence of postoperative sickness when examined by univariate analysis: patient gender, a previous history of postoperative sickness, postoperative opioid analgesics, and a history of motion sickness (table IV). When forward stepwise logistic regression analysis was applied to the uncontrolled categorical data, the following independent factors met the criteria for inclusion in the model for postoperative sickness: postoperative opioid analgesia, gender, previous history of postoperative sickness, motion sickness and an independent interaction between gender and previous sickness history (table V). Motion sickness had the weakest association and unlike the other factors did not reach statistical significance at the 0.05 level, possibly because of low power, estimated at 0.65. Assuming the same trend in the distribution of motion sickness among vomiters and non-vomiters, 800 patients would have been required to reach statistical significance.

The relative effects of these factors may be summarized by the logistic regression equation: $\text{Log}_e(p/1-p)$—that is:

$$\begin{aligned}&\text{Logit postoperative sickness} = -5.03 + 2.24\\&(\text{postoperative opioids}) + 3.97(\text{previous sickness}\\&\text{history}) + 2.4(\text{gender}) + 0.78(\text{history of motion}\\&\text{sickness}) - 3.2(\text{gender} \times \text{previous sickness history})\end{aligned}$$

where p = proportion of patients with sickness and $1-p$ = proportion without sickness. The presence of postoperative opioids, previous sickness history, female gender, and history of motion sickness are coded as 1 in the model; absence of these factors is coded as 0.

TABLE III. *Patient data (median (range)) for vomiters and non-vomiters. No significant differences within gender groups*

	Males		Females	
	Vomiters	Non-vomiters	Vomiters	Non-vomiters
Age (yr)	41 (18–63)	36 (16–78)	50 (14–72)	53 (15–77)
Wt (kg)	75 (66–86)	76 (54–128)	62 (41–98)	65 (45–82)
Duration of operation (min)	35 (30–60)	47.5 (17–115)	42 (10–73)	36 (20–115)
Duration of fast (min)	660 (370–780)	540 (320–830)	620 (380–990)	715 (380–980)
Total No. patients	9	58	31	49

TABLE IV. *Univariate analysis of the categorical data*

	Vomiter (No.)	Non-vomiter (No.)	Vomiter (%)	Non-vomiter (%)	P

TABLE V. *Logistic regression analysis of factors associated with postoperative sickness during the first 24 h after orthopaedic surgery (peripheral limb surgery). The overall odds ratio for emesis is given by the solution to: logit postoperative sickness* $= -5.03 + 2.24$*(postoperative opioids)* $+ 3.97$*(previous sickness history)* $+ 2.4$*(gender)* $+ 0.78$*(history of motion sickness)* $- 3.2$*(gender × previous sickness history) where* -5.03 *is the constant. The presence of opioids, previous sickness history, motion sickness and female gender are coded as 1 in the above equation; absence of these factors or male gender is coded as 0*

Independent factors influencing postoperative sickness	Coefficient x	SE (coeff.)	Odds ratio e^x	95% CI (odds ratio)	P
Constant	−5.03	0.92	0.01	0.001–0.039	< 0.001
Postoperative opioids	2.24	0.62	9.39	2.77–31.82	< 0.001
Previous history of sickness after anaesthesia	3.97	1.03	52.98	7.01–403.0	< 0.001
Effect of gender	2.4	0.79	11.02	2.34–51.94	< 0.005
History of motion sickness	0.78	0.57	2.18	0.71–6.68	$< 0.2 > 0.1$
Interaction of gender × previous sickness history	−3.20	1.14	0.04	0.0043–0.37	< 0.01

The log likelihood ratio test for the model produced a chi-square value of 53.5, $P < 0.001$ (5 degrees of freedom).

The most surprising finding was that, although males have an intrinsically lower probability of postoperative sickness than females, the effect of a previous history of sickness in a male increases the risk to greater than that for females (table VI).

TABLE VI. *List of probability calculations for postoperative sickness depending on the combination of independent fixed patient factors. Baseline probability represents a male with no previous history of sickness or motion sickness who did not receive opioid analgesics. Baseline odds ratio for postoperative sickness is the solution to* e^x *where* $x = -5.03$. *The odds ratios* (OR), *0.01, may be converted to a probability from* $P = OR/1 + OR$,*—that is* $P = 0.01/1.01$ = *approximately 1% probability for postoperative sickness*

Combination of independent factors influencing postoperative sickness	Probability of postop. sickness (%)	95% CI of the probability of postop. sickness
Males	1	0.1–3.8
Males with a history of motion sickness	1	0.2–9.0
Males receiving postop. opioids	5.6	2.0–25.0
Females	6.7	2.0–20.0
Males with a history of motion sickness receiving postoperative opioids	11.5	1.9–45.0
Females with a history of previous sickness	13.5	0.4–85.0
Females with a history of motion sickness	13.8	2.9–43.0
Females with previous sickness and history of motion sickness	25.1	0.9–87.0
Males with a previous history of sickness	25.7	6.5–64.0
Females receiving postoperative opioids	40.3	26.0–56.0
Males with a previous history of sickness and motion sickness	43.0	9.9–83.0
Females with previous history of sickness receiving postoperative opioids	59.3	15.9–93.0
Females with history of motion sickness receiving postoperative opioids	59.5	28.5–84.2
Females with a previous history of sickness and motion sickness receiving opioids	76.1	20.0–97.0
Males with previous history of sickness receiving opioids	76.4	49.0–91.0
Males with a previous history of sickness and motion sickness receiving opioids	87.6	53.0–97.0

DISCUSSION

Progress in identifying important factors for postoperative sickness may have become confounded by methodology that does not take account of fixed patient factors or their distribution, thereby introducing sample bias. The majority of studies have evaluated the merits of antiemetics in groups usually matched only by gender and anaesthetic technique. Further progress in the prevention of sickness may be facilitated if some method is adopted for assessing the inadvertent bias resulting from patient factors. The method we propose, based on logistic regression analysis, allows individual patient probability for postoperative sickness and the mean probability for a heterogenous group of patients to be calculated. The mean probability for sickness for groups of patients provides an additional comparison for within and between studies by examining the predicted and observed vomiting rates. Similar calculations might be preferable to historical controls for single group studies whereas, for very large studies, patients with similar probabilities may be risk-stratified into homogenous groups.

Commonly, groups of patients with many influencing factors are described as "balanced" if the frequency of factors is the same in each study group. This can be conveniently described as global balancing. However, it would appear to be inappropriate to apply global balancing to groups made up of heterogenous patients if the probabilities for sickness caused by the factors are different and logarithmically related. This is the case for probabilities derived by logistic regression. This may be illustrated by an example. Consider two groups of 10 patients, each group has five women and five men; in addition, five of these patients (males, females or both) in each group have a previous history of sickness. These two groups would be globally balanced. However, using our own model, they would not be balanced by risk if, in one group, the previous history of sickness was only present in the five males whereas, in the other group, previous history of sickness was associated with the five females. The mean probability of sickness for the group in which previous sickness is associated with males would be 16.2% whereas, in the group where it is associated with females, the mean probability for the group would be 7.25.

This study has identified previous history of postoperative sickness, female gender, history of motion sickness, an interaction between gender and previous history and postoperative opioids as fixed patient risk factors. Postoperative opioid administration was included as a fixed factor: for ethical reasons it was not controlled, and therefore it distributed according to patient requirement. There is a practical difficulty in deciding if sickness in patients who have received opioids is caused by pain, or opioids, or if it would have occurred irrespective of these two factors. Even if sickness always occurred after administration of opioids, it is still difficult to decide the time that has to elapse before a bout of sickness can be ascribed to another cause. In this study, the analysis has shown an association between sickness and receipt of opioids at some time during a 24-h period. Fortunately, 55 patients did not receive opioids by choice, and this provided a control group. Therefore it is possible to be more confident of opioids as a cause of sickness.

A criticism of this study may be the small sample from which coefficients were derived for the model. This decreases the power of the study and produces wide confidence limits, in particular when several factors are combined. We attempted to reduce our requirements for large numbers and yet maintain power by strict control of anaesthetic technique. Additionally, a surgical procedure and anaesthetic method were chosen in which the potential for confounding emetic effects related to these procedures was kept to a minimum. In spite of the small numbers, the model obtained highly significant effects from postoperative opioids, gender, previous emetic history and the interaction between gender and previous emetic history. Motion sickness failed to reach statistical significance at 0.05, possibly because of low power (0.65), but met the standard inclusion criteria for the model suggested by Hosmer and Lemeshow [12]. The reason for the lack of power could, in part, be ascribed to the study design, which allowed opioids to be administered only after the journey to the 24-h observation area; the suggested vestibular sensitization by opioids may therefore have been averted [14]. Alternatively, the effect of motion sickness may be small when compared with other factors.

The proposed model can only be considered useful if, when tested prospectively with patients other than those used in the study, it produces high correct classification rates for vomiters and non-vomiters. Therefore the statistical techniques of bootstrapping or jack-knifing which use the original data set to evaluate the ability of the model to classify patients correctly were not used. In evaluating the model, it should be noted that this study was limited to peripheral orthopaedic surgery and therefore the derived coefficients for fixed factors may need to be interpreted with caution when the model is applied to types of surgery having strong associations with postoperative sickness.

APPENDIX

The solution to the equation: $\text{Log}_e\,(p/1-p)$—that is:

Logit postoperative sickness $= -5.03 + 2.24$ (postoperative opioids) $+ 3.97$(previous sickness history) $+ 2.4$(gender) $+ 0.78$(history of motion sickness) $- 3.2$(gender × previous sickness history)

(where p = proportion of patients with sickness; $1-p$ = proportion without sickness; presence of postoperative opioids, previous sickness history, female gender, and history of motion sickness are coded as 1 in the model, absence of these factors coded as 0)

provides the basis for calculating the probability of sickness within 24 h in any particular patient.

For calculating the risk of any group of patients, the individual patient probabilities should be summed and divided by the number of patients, to provide a mean value and SD.

Calculation of individual risks is shown in examples 1 and 2.

Example 1

Baseline probability of sickness is calculated with all independent variables coded as 0:

$$\text{Logit postoperative sickness} = \text{constant} = -5.03$$

From this the odds ratio can be calculated:

$$\text{Odds ratio} = e^{-5.03} = 0.01$$

(The solution to e^x where $x = -5.03$ may be found in exponential tables.)

Derivation of the probability (P) of sickness from the odds ratio is given by:

$$P = \text{odds ratio}/1 + \text{odds ratio}$$

In the above example, P is approximately 0.01 or 1%.

Example 2

Male with a previous history of sickness and motion sickness who also received opioids.

Logit postoperative sickness

$$= -5.03 + 2.24(1) + 3.97(1) + 2.4(0) + 0.78(1) - 3.2(0 \times 1)$$
$$= -5.03 + 2.24 + 3.97 + 0.78$$
$$= 1.96$$
$$e^{1.96} = 7.09$$

probability of sickness in 24 h

$$= 7.09/8.09 = 0.876 \text{ or } 87.6\%$$

The 95% confidence limits for the probability of sickness was derived from the coefficient estimate $\pm 1.96\sqrt{\text{variance}}$ of the coefficient estimate. The upper and lower coefficient estimates thus calculated were converted to odds ratios using exponential tables, which in turn were used to calculate the 95% confidence limits for the probability of sickness.

The variance for a combination of risk factors is calculated from the sum of the independent factor estimate variances plus twice the covariances of the combined independent factor estimates. The 95% confidence limits for the probability of sickness for various independent factors are shown in table VI.

COMPARISON OF AUTOMATIC OSCILLOMETRIC ARTERIAL PRESSURE MEASUREMENT WITH CONVENTIONAL AUSCULTATORY MEASUREMENT IN THE LABOUR WARD

M. A. HASAN, T. A. THOMAS AND C. PRYS-ROBERTS

SUMMARY

We have compared two non-invasive methods of arterial pressure (AP) measurement used in labour wards: an automatic oscillometric measurement obtained by Dinamap 1846, and a conventional auscultatory measurement obtained by midwives. A total of 369 AP measurements were recorded, involving 28 normotensive and hypertensive pregnant women during labour, with or without extradural analgesia. Compared with the midwife group, the Dinamap group had a greater systolic AP, by 2.7 mm Hg ($P < 0.01$) and smaller diastolic AP, by 9.8 mm Hg ($P < 0.01$). The correlations between the two methods were highly significant, but the limits of agreement were relatively wide for both systolic and diastolic AP measurements. We conclude that a clinically important difference exists in diastolic AP measurements. Dinamap diastolic AP must be corrected using a regression equation, or simply by adding 10 mm Hg, before being compared with the available normal and hypertensive AP values. (Br. J. Anaesth. 1993; **70**: 141–144).

KEY WORDS

Arterial pressure: measurement. Equipment: manometers. Pregnancy.

Many studies have correlated the accuracy and consistency of automatic oscillometric devices with indirect auscultatory measurements [1, 2], and direct intra-arterial pressure measurements [3–9] in general adult populations [1, 3, 7], neonates [5, 6], children [2], cardiac [4, 5, 9] and critically ill patients [6, 8]. So far, studies on women in labour have not been published. A preliminary report was mentioned in a published letter [10].

Arterial pressures in labour wards are normally measured by midwives using sphygmomanometry with auscultation of phases 1 and 4 of the Korotkoff sounds to identify systolic and diastolic pressures, respectively. Published normal AP values in obstetric patients have been measured in this way. The definition, classification and subsequent treatment strategies of hypertensive disorders of pregnancy depend on pressures measured in this manner. Diastolic pressure has traditionally been the main diagnostic and prognostic indicator in obstetric patients [11] and is taken as the point of muffling (phase 4 of Korotkoff sounds) [12]—a reading which may not correspond or correlate with the true intra-arterial pressure [9] or the diastolic reading on the Dinamap 845 [1].

The introduction of automatic oscillometric measurement in labour wards should be accompanied by a knowledge of its performance in obstetric patients. Direct comparison with published (auscultatory) data may be misleading. Compensation for differences between oscillometric and auscultatory measurements concluded from studies in non-pregnant patients may not be applicable. Therefore, we have aimed to define the relation between the two measurements to enable the interpretation of oscillometric measurements in the light of available published data.

PATIENTS AND METHODS

Twenty-eight pregnant women admitted to the Central Delivery Suite at the Bristol Maternity Hospital were selected randomly for participation in the study, which was approved by the District Ethics Committee; each patient's verbal consent was obtained. The two methods studied were: Dinamap (D) measurement, an automatic oscillometric AP measurement using Dinamap 1846 (Critikon Ltd) operated by the investigator (M.A.H.); and midwife (M) measurement, a conventional auscultatory measurement taken by midwives using mercury sphygmomanometry and auscultation (Korotkoff sounds phases 1 and 4 to identify systolic and diastolic AP, respectively). No special arrangement was introduced in the selection of midwives, who were those normally involved in AP measurements in the labour ward.

Modification of sphygmomanometer tubing with the introduction of two-way stopcocks allowed the use of a single standard adult AP cuff (bladder dimensions 13×23 cm) for all the measurements with the Dinamap or sphygmomanometer. The patient's arm circumference was recorded. The Dinamap was calibrated before and at intervals throughout the study.

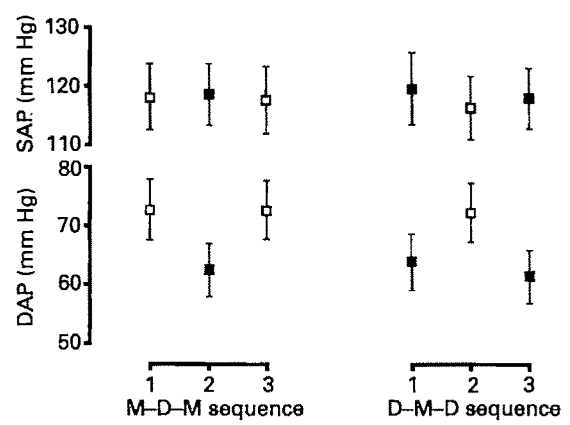

FIG. 1. Midwife (□) and Dinamap (■) measurements of systolic (SAP) and diastolic (DAP) arterial pressures taken in the order midwife–Dinamap–midwife (M–D–M) or Dinamap–midwife–Dinamap (D–M–D) (mean, 95 % confidence interval).

All AP comparisons were performed in sets of three successive measurements, comparison midwife–Dinamap–midwife (M–D–M) sequence (odd numbered sets) or Dinamap–midwife–Dinamap (D–M–D) sequence (even numbered sets). These measurement sets were repeated every 15–30 min, avoiding periods of haemodynamic instability, such as during a uterine contraction or after the injection of extradural local anaesthetic. Patients were maintained in a lateral tilt (approximately 30°) position for 5 min before and during each set of measurements, with the arm AP cuff always kept at the level of the heart. These comparison sets were repeated on up to 10 occasions for each patient. More than one midwife was allowed to make measurements in any individual patient.

Throughout the measurements, special care was taken to ensure that both the midwife and the investigator were blind to each other's recordings, which were kept separate until the measurements were completed.

Results were analysed by Minitab statistical software (version 7.2) using an IBM compatible 386 PC. Tests included: one-way analysis of variance (one factor); two-way analysis of variance (two factors), paired Student's t test, correlation and regression analyses. Limits of agreement were analysed according to Bland and Altman [13]. Probabilities of less than 0.05 were considered to be significant.

RESULTS

We studied 28 pregnant women aged 19–36 yr. Their gestations were 36–42 weeks. All were in the first stage of labour at the time of study. Their arm circumferences were 21–38 cm. Five women had auscultatory diastolic AP recorded at 90 mm Hg or greater on two or more occasions during their antenatal care. Four of these five women also had proteinuria. Seven women received extradural analgesia during part or all the period of observations.

A total of 123 comparison sets were performed (average of 4.4; range 3–9 sets per patient). Fourteen midwives participated in the study (range 1–3 midwives per patient). There were no failures of measurement with either of the two methods.

Results of AP measurements for both the M–D–M sequence and the D–M–D sequence are presented as mean and 95 % confidence intervals (fig. 1). Two-way analysis of variance of AP measurements using two factors, time (first, second, or third measurement), and method (midwife or Dinamap) showed a significant difference in the method of diastolic AP measurement. Paired Student's t tests showed significant differences between the two methods in diastolic AP measurement in the M–D–M sequence, and in systolic and diastolic AP measurements in the D–M–D sequence. Average difference (midwife minus Dinamap measurements) were -2.7 and 9.8 mm Hg for systolic and diastolic AP, respectively ($P < 0.01$).

Correlations between measurements from the two methods were $r = 0.85$ and $r = 0.834$ with regression equations of $[\mathrm{M} = 11.3 + 0.883 \times \mathrm{D}]$ and $[\mathrm{M} = 9.83 + 1.01 \times \mathrm{D}]$ for systolic and diastolic measurements, respectively ($P < 0.01$).

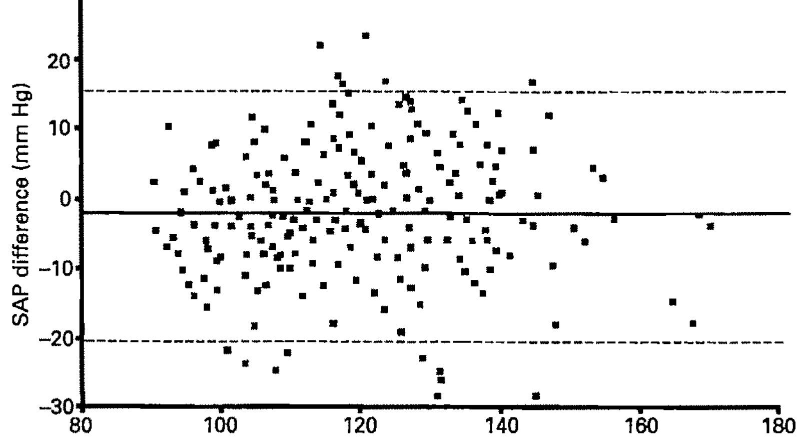

FIG. 2. Systolic arterial pressure (SAP) differences between midwife and Dinamap measurements (M−D), against average SAP of midwife and Dinamap measurements ((M+D)/2). —— = Mean of differences; ---- = limits of agreement (mean, 2 SD).

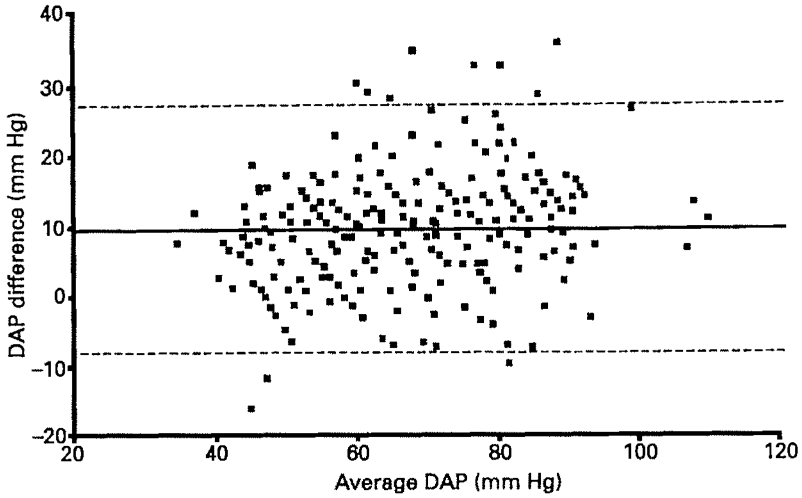

FIG. 3. Diastolic arterial pressure (DAP) differences between midwife and Dinamap measurements (M−D), against average DAP of midwife and Dinamap measurements ((M+D)/2). —— = Mean of differences; ---- = limits of agreement (mean, 2 SD).

According to the method of Bland and Altman, AP differences between the two methods were plotted against the average of both for systolic and diastolic AP, respectively (figs 2, 3). Limits of agreement between the two methods (mean (2 SD) of the difference (M minus D)) were −20.7 to +15.3 mm Hg for systolic, and −7.6 to +27.3 mm Hg for diastolic AP measurements (represented by the dotted horizontal lines). The mean differences (−2.7 mm Hg and 9.8 mm Hg for systolic and diastolic AP measurements, respectively) are represented by continuous lines. The scatter of points in figures 2 and 3 indicates lack of a change in magnitude of differences between the two methods with a change in the value of systolic or diastolic AP, respectively.

Dinamap diastolic AP measurements failed to identify auscultatory diastolic values of 90 mm Hg or greater (a threshold normally taken for close observation of AP) and 110 mm Hg or greater (a threshold taken for urgent therapeutic intervention) in 40 of 47, and in all of eight occasions, respectively. When Dinamap measurements were corrected (by adding 10 mm Hg), only 23 of 47 and four of eight such occasions failed to be identified, respectively. However, corrected Dinamap measurements identified (incorrectly) diastolic values of 90 mm Hg or greater on five occasions when auscultatory diastolic values were less than 90 mm Hg. There were no corrected Dinamap diastolic values at or greater than 110 mm Hg when corresponding auscultatory values were less than 110 mm Hg.

There were no relationships between arm circumference and systolic or diastolic AP differences between the two methods.

DISCUSSION

Our results have shown that a statistically significant and clinically important difference exists in the diastolic AP measurement between the two methods. This diastolic difference was irrespective of the order of measurements (M–D–M or D–M–D in figure 1) or the value of diastolic AP (lack of the relationship between diastolic AP difference and average diastolic AP in figure 3).

The finding of a large diastolic difference (almost 10 mm Hg) is broadly consistent with that of a recent preliminary report [10], but contrasts with results obtained from non-pregnant patients in whom Dinamap diastolic measurements were 3–4 mm Hg smaller than phase 4 auscultatory diastolic measurements [1]. This may be related to diastolic phase 4–5 discrepancy. In pregnancy, haemodynamic changes such as increased cardiac output and decreased systemic vascular resistance may affect this discrepancy. A large survey has shown, in many pregnant women, large gaps between phases 4 and 5 and sometimes very small values (reaching zero) in phase 5 [14]. The large diastolic difference in our study may be explained by the fact that midwives measure phase 4, while Dinamap diastolic measurement correlates with phase 5 diastolic AP measurement [1]. It would be interesting, but difficult, to speculate on how these two measurements would relate to direct intra-arterial measurements. Such relationships have not been studied in pregnant women and relevance of studies from non-pregnant patients is questionable.

High correlations between the two methods are not surprising, as the two methods are designed to measure the same variable. The wide limits of agreement between the two methods, shown in figures 2 and 3, reveal a considerable degree of variability which may be the result of the combined variabilities from two methods of indirect AP measurement. Repeatability of Dinamap or same midwife measurements were good. Repeated Dinamap measurements in figure 1 were not significantly different. Repeated measurements for the same midwife were almost identical (fig. 1); these may have been biased by awareness by the midwife of her initial measurement. Repeatability of measurements between different midwives was difficult to test, as different midwives were usually involved in measurements from different patients.

We conclude that Dinamap diastolic AP (if uncorrected) may be misleading when compared with the published normal and hypertensive AP values in pregnancy, especially when decisions such as diagnosis of hypertensive disorders, classification of severity of hypertension and decisions concerning subsequent treatment strategies are to be taken. The available published data on normal and hypertensive gravidas are based on auscultatory methods, and until data on Dinamap measurements are published, measurements should be corrected using the above regression equations, or more simply by adding 10 mm Hg to the Dinamap diastolic measurement. Alternatively, the definition and classification of hypertension in pregnancy may be revised when Dinamap measurements are recorded, and 80 instead of 90 mm Hg may be regarded as a diastolic AP threshold for close monitoring, and 100 rather than 110 mm Hg as a diastolic AP threshold for urgent therapeutic intervention.

USE OF ULTRASOUND TO EVALUATE INTERNAL JUGULAR VEIN ANATOMY AND TO FACILITATE CENTRAL VENOUS CANNULATION IN PAEDIATRIC PATIENTS†

P. J. ALDERSON, F. A. BURROWS, L. I. STEMP AND H. M. HOLTBY

SUMMARY

Percutaneous cannulation of the internal jugular vein in paediatric patients may be technically difficult and is prone to complications. To investigate the possibility that anatomical factors contribute to these difficulties, we used a two-dimensional ultrasound scanner to examine venous anatomy in children aged up to 6 yr. We found that 18% of our children had anomalous venous anatomy that may account for some of the difficulties reported previously. The diameter of the internal jugular vein was predicted poorly by the patient's age ($r^2 = 0.259$) or weight ($r^2 = 0.155$). We also evaluated the use of this ultrasound scanner during percutaneous central venous cannulation in neonates and infants. Determining the course of the internal jugular vein with the scanner and then marking it on the overlying skin reduced both the time and number of needle insertions required to aspirate jugular venous blood and increased the chance of a complication-free cannulation. (Br. J. Anaesth. 1993; **70**: 145–148)

KEY WORDS

Anatomy: internal jugular vein. Anaesthesia: paediatric. Veins: cannulation, ultrasound.

The approach to central venous cannulation in children depends on the experience of the operator and the indication for catheterization. Situations that require definitive intrathoracic central venous placement merit techniques in which the success rate is high (cannulation of the internal jugular or subclavian vein) [1]. Many paediatric anaesthetists avoid a subclavian approach because of the report by Groff and Ahmed [2] describing five major complications of this approach when used in 44 children younger than 2 yr. Therefore, the internal jugular vein provides the best means of reliably achieving intrathoracic venous cannulation [3, 4], although cannulation by the internal jugular route is more difficult in children younger than 3 months of age or less than 4 kg in weight [4].

Denys and Uretsky [5] reported that anatomical variation in the position of the internal jugular vein in adults may complicate venous access by this route when a landmark-guided approach was used. A similar survey in children has not been conducted; indeed, little has been published on the anatomy of the internal jugular vein in paediatric patients [6].

Recent work has shown that two-dimensional ultrasound may assist the anaethetist in cannulating the internal jugular vein in adult patients [7–9]. This technique has been shown to increase the chance of successful cannulation, particularly at the first attempt. Significant reductions in the time taken to aspirate venous blood from the internal jugular vein and in the risk of accidental puncture of the carotid artery have been reported.

We have examined internal jugular venous anatomy and the use of ultrasound to facilitate jugular venous cannulation in neonates and infants.

PATIENTS AND METHODS

Approval was obtained from the Human Subjects Review Committee of the hospital.

Part 1

The object of the first part of the study was to determine if variations in the anatomy of the internal jugular vein could account for some of the difficulty experienced during landmark-guided percutaneous jugular venous catheterization in children.

We studied 50 patients younger than 6 yr undergoing cardiac surgery. The age (days) and weight (kg) of each patient were recorded. After induction of anaesthesia and nasotracheal intubation, the patient was positioned as if for cannulation of the right internal jugular vein: a rolled towel was placed under the shoulders, the head turned to the left and the table tilted head-down by 15°. Various characteristics of venous anatomy were examined with a portable, battery-operated, two-dimensional ultrasound scanner (Dymax Corporation, Pittsburgh, PA), which has a mechanical liquid-path 7.5-MHz transducer that allows high resolution imaging of structures up to 40 mm deep to the skin. We examined the relationship between the internal

jugular vein and the carotid artery from the angle of the mandible to the clavicle, and the diameter and depth of the internal jugular vein at the level of the cricoid cartilage. Diameter and depth were measured to the nearest 0.5 mm with a pair of calipers applied to the image on the scanner screen.

Part 2

The object of the second part of the study was to determine if the use of such an ultrasound scanner could facilitate percutaneous internal jugular vein cannulation in neonates and infants.

We studied 40 patients younger than 2 yr who would undergo percutaneous insertion of an internal jugular cannula during cardiac surgery. None had undergone prior cardiac surgery or jugular cannulation. They were allocated randomly to one of two groups: group A = cannulation guided by anatomical landmarks; group B = cannulation guided by ultrasound.

All central venous cannulations were carried out after induction of anaesthesia and nasotracheal intubation. The patient was positioned for cannulation of the right internal jugular vein with a rolled towel under the shoulders, the head turned to the left and the table titled head-down by 15°. For those in group A, the two heads of the sternomastoid were palpated, the position of the carotid artery verified and the cannula inserted at the junction of the two heads of the sternomastoid angled toward the ipsilateral nipple. For those in group B, the ultrasound scanner was used to visualize the internal jugular vein so that its projection could be marked onto the overlying skin with a pen; this line then served as a guide for cannulation.

In every patient, cannulation was carried out by an experienced cardiac anaesthetist who used a 21-gauge, 4-cm needle to locate the internal jugular vein. A 16-gauge polyurethane double-lumen catheter was positioned using a Seldinger wire passed through the 21-gauge needle. The time from the initial skin puncture to the aspiration of venous blood was recorded, together with the number of needle insertions required to locate the vein. Details of any complications were noted.

Data analysis

Data are presented as arithmetic means (SD). The lines of best fit for the graphical figures were determined by linear regression analysis. Parametric data were analysed by one-way analysis of variance and the Student–Newman–Keuls test. $P < 0.05$ was considered to be significant.

RESULTS

Part 1

The patients ranged in age from 3 days to 5.5 yr and in weight from 2.7 to 22 kg. None of the children had been born prematurely.

In 82 % of patients, the internal jugular vein ran antero-laterally to the carotid artery. In 4 %, the vein was in a similar position relative to the carotid artery, but was of unusually small diameter (defined as ≤ 3 mm for neonates and infants and as ≤ 5 mm for older children). In 10 %, the vein ran so medially that it entirely overlay the carotid artery; in 2 % the vein ran widely lateral to the carotid artery. In the remaining 2 %, the vein could not be seen.

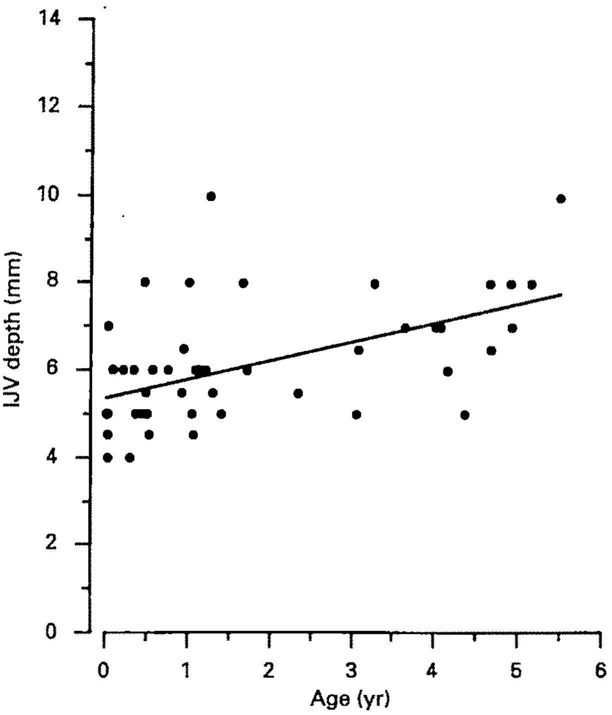

FIG. 1. Relationship of the depth of the internal jugular vein (IJV) to age. $r^2 = 0.290$.

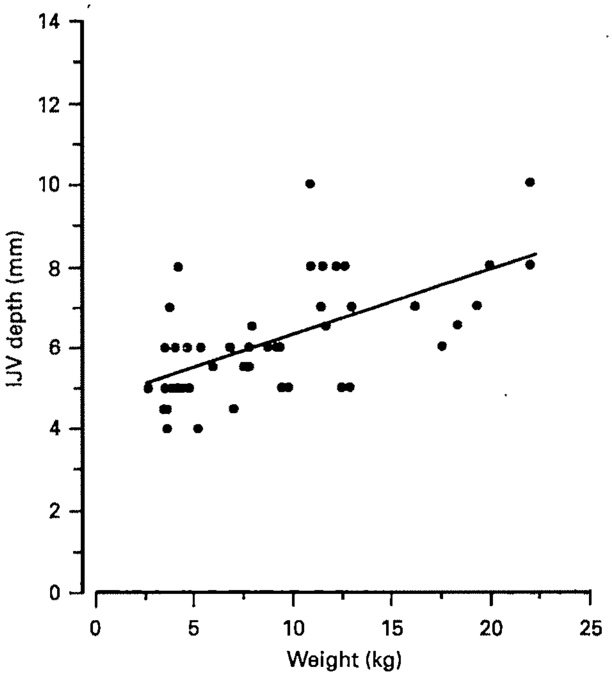

FIG. 2. Relationship of the depth of the internal jugular vein (IJV) to weight. $r^2 = 0.379$.

At the level of the cricoid ring, the vein was seen 4–10 mm below the surface of the skin. This distance tended to increase with both age and weight, the better correlation being with weight (figs 1, 2). At the same site, the vein varied in diameter from 2.5 to 12 mm; again, vein size tended to increase with both age and weight, but correlations were poor (figs 3, 4).

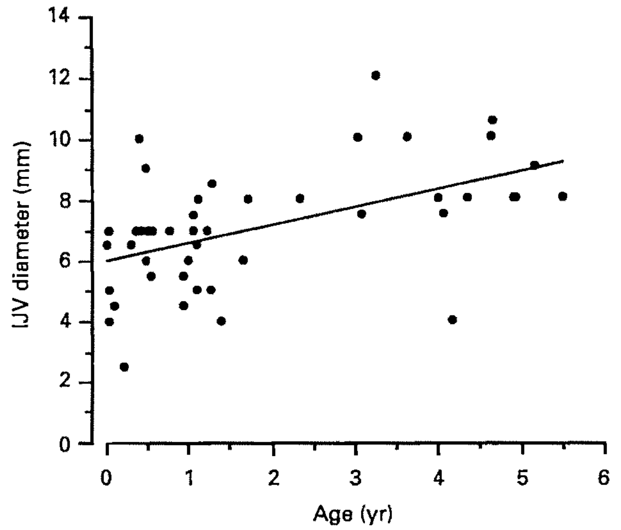

FIG. 3. Relationship of the diameter of the internal jugular vein (IJV) to age. $r^2 = 0.259$.

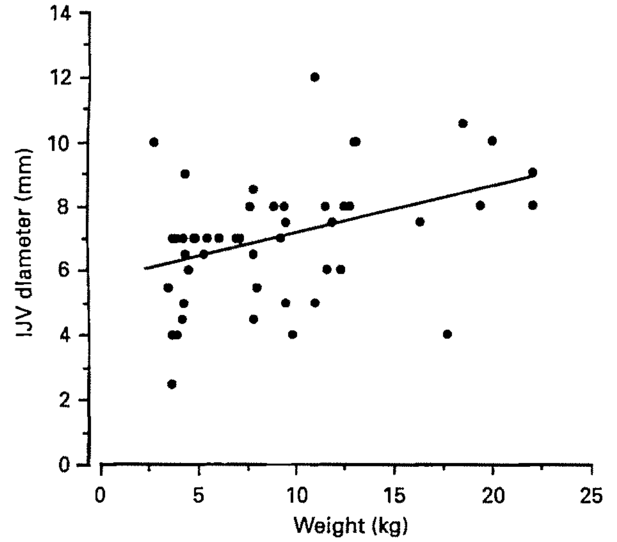

FIG. 4. Relationship of the diameter of the internal jugular vein (IJV) to weight. $r^2 = 0.155$.

TABLE I. *Comparison of landmark-guided and ultrasound-guided cannulation techniques (range or mean (SD)).* $P < 0.05$ compared with group B*

Access data	Group A Landmark-guided	Group B Ultrasound-guided
Success rate	16/20	20/20
Time taken (s)	6–170	2–90
Time taken (s)	56.4 (48.9)*	23.0 (27.4)
No. needle insertions	2.0 (1.0)*	1.35 (0.7)

Part 2

The two groups were similar in age and weight (group A: 281 (218) days, 6.8 (2.5) kg; group B: 258 (170) days, 6.6 (2.5) kg). Each group contained three neonates and 17 infants.

Table I compares the success of the two cannulation techniques. In four of the children assigned to group A, the internal jugular vein was not located. In the other 16 patients, it took significantly longer ($P = 0.011$) to locate the vein than in those in group B in whom ultrasound was used to mark the course of the vein. In addition, significantly more needle insertions ($P = 0.018$) were needed to locate the vein in group A patients.

The most common complication during cannulation was inability to pass the Seldinger wire into the superior vena cava after venous blood had been aspirated. This occurred eight times in group A and three times in group B. Carotid artery puncture occurred in two patients in group A and in one in group B. Overall, eight cannulations in group A and 16 in group B were uncomplicated ($P < 0.05$).

DISCUSSION

Eighteen percent (nine of 50) of the patients younger than 6 yr in our study had anatomical factors that may complicate a landmark-guided approach to the internal jugular vein.

In a previous prospective study [10] of landmark-guided percutaneous internal jugular venous catheterization in children aged up to 14 yr, the right internal jugular vein was cannulated successfully in 31 of 52 patients (59.6%), and the left in nine of 52. Greater success rates were obtained with children older than 2 yr, although this finding was not statistically significant. The complications noted included 12 (23%) carotid artery punctures. In a retrospective study [11] of percutaneous jugular venous catheterization in 200 children, 45% of whom were 5 yr or younger, the internal jugular vein was cannulated successfully in 109 of 128 patients (85.2%). The recent Osaka study [4] of 106 children aged up to 7 yr reported that the rate of successful cannulation on the first attempt, defined so that it included multiple needle insertions at a single site, was 78.3%. Complications included 12 (11.3%) arterial punctures.

From these studies it appears that the proportion of patients in whom percutaneous internal jugular cannulation is difficult is of the same magnitude as the proportion of patients in whom the relationship between the vein and the carotid artery is anomalous in some way.

Venous blood is often identified during cannulation as the needle is drawn back through the vein. As we have found that the carotid artery runs posterior to the vein in 10% of the children in our study, we suggest that the risk of carotid puncture is of this magnitude. This risk appears to be similar to the rates of arterial puncture in the research cited above.

There is little information on the diameter of the internal jugular vein in childhood. One anatomical survey [6] included 11 children aged from 13 months to 16 yr. This subset showed a poor correlation between the diameter of the internal jugular vein and age, height, weight or body surface area. The smallest vein seen in these children was 6.6 mm in diameter when the child was in the Trendelenburg position. Their anatomical findings are similar to those reported here.

Inability to demonstrate an internal jugular vein in 2% of our patients was surprising: congenital absence of the internal jugular vein is extremely rare, particularly in the absence of other cerebrovascular malformations. There are two possible explanations for our result: the ultrasound scanner could not identify the internal jugular vein because the diameter was so small, or the ultrasound probe occluded the vein because, despite our efforts, the probe exerted excessive pressure on the neck.

In comparison with group A in our study, both the time required to locate the internal jugular vein and the number of needle insertions required were less in group B. These findings concur with those of earlier reports in adult patients [7–9], indicating that ultrasound guidance improved the speed and safety of central venous access. In previous studies the ultrasound probe was wrapped in a sterile sheath so that it could be manipulated in the sterile field by the operator during cannulation. Although this technique allows the operator to guide the needle into the vein visually, it requires the extra expense of the sterile sheath and a considerable degree of manual dexterity in paediatric practice. We found that our simplified approach, without the sheath, was also effective.

Using the ultrasound scanner, we found that our complication rate was 20%, compared with 60% when using the landmark approach. Our most common complication was inability to insert the Seldinger wire into the superior vena cava. Other studies have not reported this as a complication, although it can greatly increase the overall time required to place the central catheter. The reason for the high incidence of difficulty inserting the Seldinger wire in neonates and infants is probably the ease with which the needle tip becomes displaced from the lumen of the vein as the syringe is disconnected from the needle. We were unable to show that the rate of carotid puncture was reduced with the use of ultrasound because of our small sample size.

ACKNOWLEDGEMENTS

We thank Dymax Corporation for loan of the Site Rite ultrasound scanner for the duration of these studies.

METABOLIC EFFECTS OF CORRECTIVE SURGERY IN INFANTS AND CHILDREN WITH CONGENITAL HEART DEFECTS

K. PUHAKKA, J. RÄSÄNEN, M. LEIJALA AND K. PELTOLA

SUMMARY

We have measured oxygen consumption and carbon dioxide production by indirect calorimetry in 25 infants and children immediately before and after surgical correction of congenital cardiac malformations. Surgical correction of the cardiac defect caused a decrease in oxygen consumption towards normal. Greatly increased oxygen consumption values were observed before surgery in the infants with a large left-to-right intracardiac shunt and heart failure and the highest reduction in metabolic rate, up to 43%, was observed in these infants. The results indicate that corrective surgery for congenital cardiac malformations reduces the load on the cardiopulmonary system immediately after operation. (Br. J. Anaesth. 1993; **70**: 149–153)

KEY WORDS

Heart: congenital defects. Oxygen: consumption. Surgery: cardiac, paediatric.

In congenital heart disease, oxygen consumption is increased in patients with intracardiac or extracardiac left-to-right shunt and excessive pulmonary flow, while those with right-to-left shunt or no shunt have normal or reduced pulmonary flow and normal or reduced oxygen consumption [1–6]. Infants with a large intracardiac left-to-right shunt require early surgical intervention because of failure to thrive and congestive heart failure.

Previous reports indicate that the secondary metabolic effects of congenital cardiac defects are frequently reversible if the lesion is surgically corrected [7–10]. Surgical correction of the cardiac malformation alters the relationship between the pulmonary and systemic flows towards that prevailing in the normal circulating system, and should also adjust the metabolic rate. The metabolic changes that take place during postoperative recovery have not been well documented, however.

This investigation was designed to assess the effect of corrective operations on oxygen consumption and carbon dioxide production immediately after surgery in infants and children with cyanotic and acyanotic cardiac lesions.

PATIENTS AND METHODS

We studied 25 consecutively admitted infants and children undergoing elective open heart operations for the correction of congenital heart defects. Patients who needed supplementary oxygen therapy or mechanical ventilation before surgery were excluded. The investigation was approved by the Institutional Ethics Committee of Helsinki University Children's Hospital, and informed consent was obtained from one or both parents of each patient.

The patients fasted for 4–5 h and were premedicated with oral flunitrazepam 100 μg kg^{-1} (maximum dose 2 mg) before operation. While the children were asleep, oxygen consumption and carbon dioxide production during spontaneous breathing were measured using an open system indirect calorimetry device [11] (Datex Deltatrac Paediatric, Datex Inc., Helsinki, Finland) in which the ventilatory gases were collected using a canopy from which a constant flow of gas (10 litre min^{-1}) was drawn into the monitor. The gas lost from the canopy was replaced by an inflow of room air through a vent at the top, and inspiratory gas fractions were sampled outside the canopy at the vent inlet. The differences between the inspired and expired oxygen fractions were measured using a fast-response, paramagnetic differential oxygen sensor (OM-101, Datex/Instrumentarium, Helsinki, Finland) and the inspired and expired carbon dioxide fractions were measured using an infra-red carbon dioxide sensor. The calorimeter was calibrated before each measurement according to the instructions supplied by the manufacturer.

The canopy covered the child's head, shoulders and upper chest, and the escape of the expiratory gases from under it was prevented by a soft plastic skirt which was attached to the rim of the canopy. After a 10-min stabilization period, oxygen consumption and carbon dioxide production were measured once every 1 min for 15 min. If the patient's movements interfered with the measurement, additional sedation with i.m. ketamine 3 mg kg^{-1} or rectal methohexitone 10 mg kg^{-1} was given and data collection was restarted. Arterial blood oxyhaemoglobin saturation was monitored continuously using a pulse oximeter. Heart rate,

Correspondence to K.P.

ventilatory frequency, rectal temperature and room temperature were recorded during the collection of ventilatory gases. Blood haemoglobin concentration, measured the day before the operation, was obtained from the medical records.

After the operation, the measurements were repeated after tracheal extubation as soon as the patient maintained an arterial blood oxyhaemoglobin saturation greater than 90% when breathing room air. The measurements were performed during the late morning hours, when the child was asleep or sedated with i.v. morphine 100 μg kg^{-1} or flunitrazepam 30 μg kg^{-1}.

A two-way repeated measures analysis of variance was used to test the statistical significance of the effects of age and type of malformation on the variables. Student's *t* test for paired observations was used to assess the statistical significance of changes within the groups; probability values < 0.05 were considered statistically significant.

The measured values for oxygen consumption ($\dot{V}O_2$) and carbon dioxide production ($\dot{V}CO_2$) were compared with the expected values calculated from the regression equation published by Lindhal [12] ($\dot{V}O_2$ ml min^{-1} = 5.0 × weight (kg) + 19.8; $\dot{V}CO_2$ ml min^{-1} = 4.8 × weight (kg) + 6.4).

Multiple linear regression analysis was used to evaluate the influence of age, type of cardiac malformation, duration of cardiopulmonary bypass, time of postoperative data collection, preoperative heart failure, rectal temperature and change in ventilatory frequency and heart rate on the change in oxygen consumption. The results are expressed as mean (SD).

RESULTS

The patients ranged in age from 2 months to 10 yr. Fifteen of the 25 patients had a left-to-right intracardiac shunt, one had isolated aortic stenosis and nine had a cyanotic cardiac malformation (tables I, II).

Two patients (Nos 5 and 9) received rectal methohexitone and four (Nos 3, 6, 13 and 24) received i.m. ketamine as additional sedation for the measurements before surgery. Fifteen patients had been treated for cardiac failure before surgery and 20 needed inotropic support at the time of postoperative data collection.

The measurements after surgery were performed between the first and the 15 days after operation. Two patients were receiving total parenteral nutrition at this time, and the other 23 were receiving enteral feeding supplemented with 5–10% glucose infusions. Mean room temperature was 24.9 (1.6) °C during all the examinations.

The patients were classified into two subgroups according to the presence or absence of a cyanotic cardiac lesion before surgery. Changes in the variables in the two groups are shown in table III.

The mean oxygen consumption of the infants aged 1 yr or less was 11.0 (3.3) ml kg^{-1} min^{-1} before operation and 7.8 (1.3) ml kg^{-1} min^{-1} afterwards ($P < 0.01$) and that of the children older than 1 yr

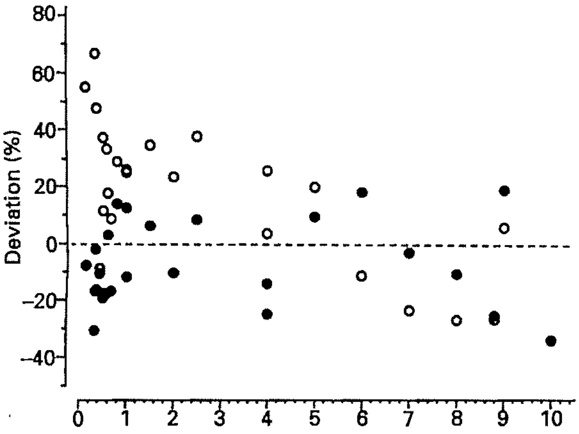

FIG. 1. Plots of the difference between observed and expected oxygen consumption (Deviation) before (○) and after (●) corrective surgery, against age in 25 children with congenital cardiac malformations.

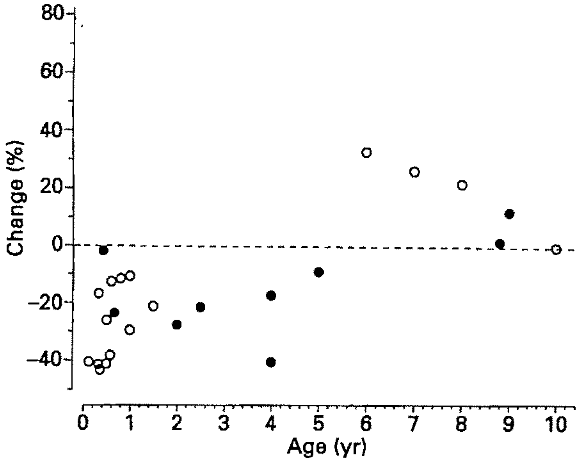

FIG. 2. Effect of surgical correction of cardiac malformation on oxygen consumption (Change) in children with cyanotic (●) ($n = 9$) and acyanotic (○) ($n = 16$) heart disease.

was 6.5 (2.0) ml kg^{-1} min^{-1} before and 6.0 (1.3) ml kg^{-1} min^{-1} after operation. The preoperative oxygen consumption of the infants was significantly greater than that expected for their weight (8.6 (1.1) ml kg^{-1} min^{-1}) ($P < 0.01$), but there was no longer any significant difference after the corrective operation. Both preoperative and postoperative oxygen consumption were similar to the expected values (6.3 (0.4) ml kg^{-1} min^{-1}) (ns) in the case of the children aged more than 1 yr. The deviations of oxygen consumption values from the expected values are presented in figure 1.

The changes in carbon dioxide production in response to the operation were similar to those in oxygen consumption.

The mean decline in oxygen consumption for all patients after surgery was 15 (22) %, range −43 % to +33 % ($P < 0.01$) (fig. 2), and that in carbon dioxide production 17 (22) %, range −46 % to +35 % ($P < 0.001$).

The type of cardiac malformation (cyanotic/acyanotic) did not correlate with the change in oxygen consumption (fig. 2), the only significant predictor of the latter being age ($r = 0.72$). The decrease in oxygen consumption after surgery was greater in the 15 patients with cardiac failure before surgery (23 (18) %) than in the 10 without cardiac failure (4 (24) %) ($P < 0.05$).

DISCUSSION

Oxygen consumption and carbon dioxide production were measured in 25 infants and children with congenital heart defects immediately before and after surgical correction of cardiac malformation in order to evaluate changes in metabolic rate. Although an increased incidence of preoperative hypermetabolism was found in the infants and small children, a quick reversion to normal values occurred after the operation. Comparison of the measured oxygen consumption and carbon dioxide production values with those expected in healthy, anaesthetized, spontaneously breathing children of comparable weight [12] revealed an abnormal increase in the metabolic rate, of a type which could only have resulted from measurement error or some factor related to the cardiopulmonary disease.

All measurements were performed by one of two investigators (K.P., J.R.) using the same open system indirect calorimetry device, which was calibrated carefully before each measurement. A validation of this device has been published previously [11]. It is therefore unlikely that any difference in the equipment or its use could have led to a systematic error.

There are several factors which may alter the metabolic rate. All our patients were sedated and sleeping during both measurements in order to standardize the conditions, as activity can quickly increase body oxygen consumption [13–16] and sedation reduces it by 26–34% [15, 17]. The type of sedation has also been shown to influence oxygen consumption during cardiac catheterization [18]. Additional sedation was selected according to the patient's clinical condition, to restore spontaneous breathing and stable haemodynamic state and to eliminate active muscle movements. Theoretically, ketamine increases the metabolic rate [18], but we used a small dose without atropine. The overall result—a decrease in metabolic rate—does not alter, however, even if these patients are excluded. Methohexitone, in contrast, may reduce metabolism. In spite of this, patients Nos 5 and 9 had an abnormally increased oxygen consumption before surgery and there was a decrease after surgery.

Body temperature [19] and environmental temperature [20, 21] are also known to modify metabolism. Rectal temperature was the same or greater after the operation in all the patients and therefore cannot explain the decrease in metabolic rate (table III). Room temperature was comparable for both measurement periods and the patients were dressed and covered in a similar way. Bed rest and inadequate caloric intake reduce the metabolic rate in healthy adults [22, 23] and a meal can increase it for several hours [13]. However, the present patients had been fasting for 4–5 h before the preoperative examination. Admittedly, the food intake was not standardized for the postoperative measurement, and some measurements were performed soon after a meal, but any errors resulting from differences in feeding would have increased the postoperative oxygen consumption in relation to the preoperative values, and thus cannot explain the observed reduction in oxygen consumption.

Similarly, surgical trauma initiates many neuroendocrine responses which tend to increase the metabolic rate during postoperative recovery from major surgery [19, 24], and infants and children have been shown to have greater hormonal responses of shorter duration than adults after cardiac surgery [25–27]. The day of postoperative measurement in this series varied between the first and the 15th, depending on patient's clinical condition. Nine patients were examined during the first 3 days after the operation, when the effect of surgical trauma on the metabolic rate is greatest. In three of these (patients Nos 21, 22, 23, aged between 6 and 8 yr), the metabolic rate was normal before surgery and increased afterwards, secondary to surgical stress. Differences in neuroendocrine function thus do not explain the decrease in oxygen consumption resulting from the operation.

It has been shown that patients with congenital heart defects involving high pulmonary flow, large left-to-right shunt and cardiac failure have increased oxygen consumption because of increased cardiopulmonary work [3–5, 28, 29] and this was seen also in our study, in which the decrease in metabolic rate occurred exclusively in the infants and small children with congestive heart failure requiring treatment before the operation. Although infants with cyanotic cardiac malformations have been shown to have smaller oxygen consumption in relation to body weight than normal infants, because of limited oxygen transport capacity and reduced pulmonary blood flow [1, 2, 4–6], our patients with cyanotic cardiac malformations had increased or normal oxygen consumption before surgery.

Decreased oxygen supply cannot explain the decrease in oxygen consumption after the operation in this study, because the patients were in good clinical condition at the time of the postoperative examination, spontaneously breathing room air, and in a resting state. Our findings suggest that the metabolic effects of corrective operations are more pronounced in small children than in older ones, but this seems to be a consequence of selecting patients with symptoms of cardiopulmonary failure for operation at an early age. These patients appear to have an increased metabolic rate in response to excessive cardiopulmonary work [29]. Corrective surgery relieved the increased cardiopulmonary load within a few days, thereby causing a reduction in total body oxygen consumption. This improvement in metabolic rate may explain the greater weight gain of infants and children after corrective surgery, as observed in earlier long-term follow-up studies [7, 9].

EFFECT OF NITROUS OXIDE ON CEREBRAL BLOOD FLOW IN NORMAL HUMANS

L. M. FIELD, D. E. DORRANCE, E. K. KRZEMINSKA AND L. Z. BARSOUM

SUMMARY

We have studied the effect of nitrous oxide on cerebral haemodynamics in 24 healthy male volunteers. Hemispherical cerebral blood flow (CBF) was measured using the xenon-133 inhalation technique, blood flow velocities in the right middle cerebral artery were calculated using transcranial Doppler ultrasound and the pulsatility index (PI)—the inverse of which is theoretically proportional to flow in the vessel under investigation—was derived from analysis of the spectrally analysed velocity pulse wave form obtained from the middle cerebral artery. Each variable was measured with the subject inhaling 100% oxygen (1st baseline), 30% nitrous oxide in oxygen, 100% oxygen (2nd baseline) and 60% nitrous oxide in oxygen. CBF was significantly greater with 30% ($0.01 > P > 0.001$) and 60% nitrous oxide ($P < 0.001$) compared with baseline, although the difference between 30% and 60% nitrous oxide was not significant. Changes in 1/PI correlated closely with those in hemispherical CBF. Blood flow velocities increased significantly with 30% ($P < 0.001$) and 60% nitrous oxide ($0.005 > P > 0.001$), the difference between 30% and 60% nitrous oxide also being significant ($0.005 > P > 0.001$). We observed a plateau in the change in CBF caused by nitrous oxide and suggest that this may be explained by activation of intact autoregulative mechanisms in healthy human brain. (Br. J. Anaesth. 1993; **70**: 154–159)

KEY WORDS

Anaesthetics, gases: nitrous oxide. Brain: cerebral blood flow. Measurement techniques: transcranial Doppler ultrasound.

After conflicting reports on the influence of nitrous oxide on cerebral haemodynamics in the 1960s and 70s [1–3], there has been much debate as to the advantages and disadvantages of this agent in neurosurgical anaesthesia [4]. In particular, there is accumulating evidence to show that nitrous oxide increases cerebral blood volume [5], intracranial pressure (ICP) [6–8] and cerebral blood flow (CBF) [7–13]. This is undesirable in neurosurgical practice and may adversely affect outcome. The evidence to date has been gathered from animal experiments [2, 3, 5, 8–10, 12, 13] and studies in patients with neurological disease [6, 7] and in normal anaesthetized humans [1, 11]. Species differences, intracerebral pathology and drug interactions may have had an important bearing on the results obtained.

The aims of our study were threefold: first, to identify the influence of nitrous oxide, second, to examine the effect of altering nitrous oxide concentrations and third, to compare the effects of large (60%) and small (30%) concentrations of nitrous oxide on CBF and transcranial Doppler ultrasound measurements (blood flow velocities in the right middle cerebral artery and the Pulsatility Index) in normal individuals.

SUBJECTS AND METHODS

After approval by the hospital's Ethics Committee, we studied 24 healthy male volunteers (mean age 28.5 yr, range 19–38 yr) with their informed consent. Each submitted to a routine clinical history, 12-lead ECG and haematological screen. In light of the known effects of nitrous oxide on haemopoiesis [14], the presence of an abnormal full blood count would have led to exclusion from the study. They were starved for 6 h before the study and requested not to smoke or consume caffeine-containing drinks for 12 h preceding the measurements, as both have been shown to affect CBF [15, 16].

Procedure

Three variables were examined in each volunteer: CBF was measured using the xenon-133 inhalation technique [17]; blood flow velocities, calculated from the time-averaged mean velocity (*V*tam) taken over the cardiac cycle in the right middle cerebral artery (MCA), were monitored using transcranial Doppler (TCD) ultrasound [18]; and the Pulsatility Index (PI)—defined as systolic velocity minus diastolic velocity divided by mean velocity—was calculated (Doptek Spectrascan with microcomputer) from the spectrally analysed pulse wave velocities obtained from the MCA. The inverse of this variable (1/PI) is theoretically proportional to flow [19]. *V*tam and PI were averaged over at least nine cardiac cycles to allow for normal variations, particularly respiratory variations. These variables were assessed with the following gas mixtures:

baseline 100% oxygen; 30% nitrous oxide in oxygen; 100% oxygen to confirm a return to baseline values; and 60% nitrous oxide in oxygen. Each subject acted as his own control. The sequence of gas mixtures was performed once in each volunteer.

The anaesthetic system used was a simple circle system (fig. 1); particular features comprised an 18-litre reservoir bag, an injection port for xenon-133 placed close to the subject and a small limb for extraction of expired air. An Air Force style mask was adjusted for comfort and secured by a harness to eliminate leaks. Each volunteer was allowed to familiarize himself with the circuit and mask before the first measurements were made.

The following procedure was adopted for each of the four measurements:

Step 1—A period of equilibrium for the appropriate gas mixture. During this time, the volunteer was allowed to breathe the gas mixture with the system exhausting to atmosphere. This took between 5 and 15 min, the first baseline run being the longest in order to allow for nitrogen washout as in any circle system.

Step 2—A period of equilibrium for xenon-133 within the system and the lungs. During this phase the system was closed to atmosphere and xenon-133 3 mCi was injected into the system. This phase lasted 2 min.

Step 3—A period of washout of xenon-133 from the cerebral hemispheres (detected by scintillation counters placed over the cranium) with the system exhausting to atmosphere; this phase lasted 2–3 min. CBF was calculated using three-dimensional deconvolutional analysis of the cerebral and lung (expired air) xenon-133 washout curves obtained as described by Wyper, Lennox and Rowan [17]. At the end of this period, the gas under study was cleared from the circuit and substituted by the next mixture to be examined.

On completion of this procedure, the volunteer was allowed to breathe 100% oxygen in order to aid recovery from the effects of 60% nitrous oxide.

Flow velocities in the MCA were monitored throughout the study (transcranial Doppler EME TC-2-64), the signals being recorded on magnetic tape. A 2-MHz pulsed Doppler transducer was placed on the skin surface just above the right zygomatic arch where the temporal bone is relatively thin, and the MCA insonated.

Other variables monitored continuously were: peripheral oxygen saturation (Sp_{O_2}), heart rate (HR), inspired oxygen concentration, end-tidal carbon dioxide $P\text{E}'_{CO_2}$ (Ohmeda OxiCap 4700) and non-invasive mean arterial pressure (MAP) (Nippon Corporation).

Comments made by the volunteers on the effects of nitrous oxide and observed effects of 30% and 60% nitrous oxide were recorded. All the results are expressed as the difference and the mean difference of the measurements obtained in order to compensate for age related variations in cerebral haemodynamics bearing in mind the 20-yr age range in our volunteers.

Statistical analysis

Data were analysed by Student's t test. The mean differences are reported with one SEM and $P < 0.05$ was taken as statistically significant. The 95% confidence limits on those means are also given. All calculations were made using Unistat III (Unisoft Ltd) on a Caf computer.

RESULTS

Of the 24 volunteers, 20 completed the study and four withdrew at various stages, for the following reasons: breathholding during the 60% nitrous oxide measurement, hysterical and uncontrollable laughter during the 60% nitrous oxide measurement, withdrawal of consent after distressing experiences caused by 30% nitrous oxide and severe abreaction during the 30% nitrous oxide measurement.

Comparison of 100% oxygen and 30% nitrous oxide, 100% oxygen and 60% nitrous oxide, and 30% and 60% nitrous oxide has given us differences and mean differences in CBF, *V*tam, 1/PI, HR, MAP and $P\text{E}'_{CO_2}$ (tables I–IV). Sp_{O_2} remained within

the range 97–100% in all subjects. Analysis of data obtained for the 100% oxygen measurements used values recorded during the first baseline run. Comparison between the two 100% oxygen measurements showed no statistically significant difference in the variables examined (table V) confirming a return to normal baseline values after the 30% nitrous oxide measurement.

There was no significant change in MAP and *P*E'_{CO_2} during the study (table IV). Heart rate increased significantly with 60% nitrous oxide compared with 100% oxygen and 30% nitrous oxide, but not with 30% nitrous oxide compared with 100% oxygen (table IV). There were significant increases in CBF and 1/PI with 30% nitrous oxide compared with baseline. The increases with 60% nitrous oxide were not greater than those observed with 30% nitrous oxide (tables I, III). *V*tam increased significantly with 30% nitrous oxide compared with baseline followed by a further significant increases in this variable with 60% nitrous oxide (table II).

Of increasingly apparent interest during the course of the trial were the potent behavioural and psychological effects of nitrous oxide. Most enjoyed the experience, although some found it distressing. All volunteers were anxious, in spite of attempts to reduce the inevitable apprehension that participation in such a study would generate. All experienced amplification of sound. Thirteen of the remaining 20 volunteers dreamed with 60% nitrous oxide and one dreamed with both 30% and 60% nitrous oxide.

We have compared data from dreamers and non-dreamers, but care must be taken in interpreting this analysis, as poor recall of events was frequent and, of those who claimed not to have dreamed, several may simply not have remembered. Comparison was limited to the 60% nitrous oxide measurement as there was only one incidence of dreaming with 30%. In contrast with non-dreamers, CBF, *V*tam and 1/PI increased in all subjects who experienced dreams. Only the increase in 1/PI was statistically significant (table VI), although the 95% confidence limits suggest that, with greater numbers, the increase in CBF and *V*tam would also be significant.

DISCUSSION

We have shown that nitrous oxide administered in oxygen increased CBF in normal humans. A constant *P*E'_{CO_2} and, by implication, a constant arterial carbon dioxide tension, were maintained in the presence of good oxygenation and a stable arterial pressure and thus the known effects of hypercapnia, hypoxia and fluctuations in arterial pressure on cerebral haemodynamics were thereby excluded.

Anxiety is known to increase CBF [20] and all volunteers were apprehensive to a greater or lesser

degree. This was countered by using each subject as his own control. We do not believe that apprehension increased with inhalation of 30% nitrous oxide. The introduction of 60% nitrous oxide, however, coincided with a statistically significant increase in heart rate; this is explained most easily by increasing levels of anxiety. We cannot exclude this as having an influence on the results obtained. Dreaming is accompanied by a marked increase in mental activity and comparison between dreamers and non-dreamers suggests this may also have contributed, albeit insignificantly, to the observed increase in CBF caused by 60% nitrous oxide. When considering the influence of increasing anxiety and dreaming on cerebral haemodynamics, it is important to remember that the greatest changes occurred with 30% nitrous oxide when these factors were absent. Thus any contribution to the further insignificant increase observed with 60% nitrous oxide is unlikely to be important. Our results, interpreted with analysis of the spectrally analysed pulse wave velocities (fig. 2) suggest that vasodilatation was the immediate cause of increased CBF; this supports much of the available evidence [6, 21, 22]. However, we can only speculate on the mechanism by which nitrous oxide causes vasodilatation. A review of the literature leads us to support the theory that nitrous oxide acts predominantly by direct action on vascular smooth muscle or endothelium [22, 23]. The results of recent research into the properties of nitric oxide may shed some light on the mode of action of nitrous oxide. Nitric oxide is believed to be endothelium-derived relaxing factor (EDRF) [24], which is released from endothelial cells in response to stimulation by vasoactive substances. Synthesis of nitric oxide certainly appears to have an important influence on both basal tone and response of large cerebral arteries to acetylcholine *in vivo* [25]. Nitric oxide, in addition to other vasodilators such as nitroprusside and glyceryl trinitrate, facilitiates conversion of glyceryl triphosphate to cyclic glycerol monophosphate which leads to vascular smooth muscle relaxation [26]. There is no evidence to support the theory that nitric oxide and nitrous oxide have similar modes of action, but the possibility makes interesting speculation. Alternatively, nitrous oxide may cause vasodilatation indirectly by increasing the cerebral metabolic rate for oxygen ($CMRo_2$), although the evidence for this is conflicting [23]. Nitrous oxide has been shown to increase $CMRo_2$ markedly [10], moderately [9, 11] or not at all [3, 8], whilst consistently increasing CBF to a similar degree. Furthermore, in the isolated perfused brain preparation [22], cerebrovascular

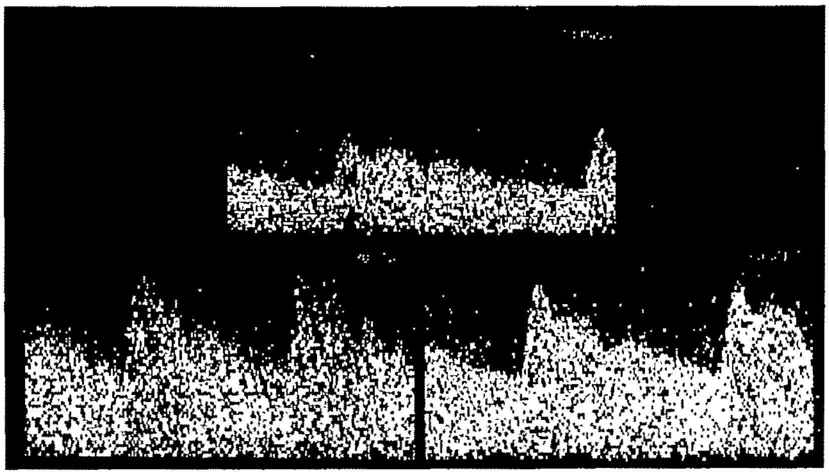

FIG. 2. MCA transcranial Doppler ultrasound waveforms showing changes in pulse wave velocities (*Y* axis) with time (*X* axis).

tone decreased significantly with CMRo$_2$ remaining unchanged. This suggests that, in the presence of nitrous oxide, changes in CBF are independent of changes in CMRo$_2$.

The most interesting aspect of our results is the existence of a plateau to the increase in CBF caused by nitrous oxide at or before a concentration of 30 %, confirmed with 1/PI. The only previous suggestion that nitrous oxide may have a biphasic effect came from Cole and Shapiro, who investigated the influence of increasing concentrations of nitrous oxide on cerebral and spinal cord glucose metabolism in the rat [27]. They found that, whereas 30 % nitrous oxide increased metabolism, 60 % nitrous oxide had the opposite effect. In this study, enflurane was administered concurrently with nitrous oxide in varying concentrations to maintain a constant MAC value and this may have affected the results. Whether we accept Cole and Shapiro's findings as having relevance to our study depends on whether we recognize a strong link between CBF and cerebral metabolism in the presence of nitrous oxide. We believe autoregulation of the small calibre vessels of the brain is the most likely explanation for the plateau described. This is supported by the fact that nitrous oxide does not affect autoregulative mechanisms [28]. However, the same assumption cannot be made of the large-calibre vessels. Unlike CBF, *V*tam increased steadily and significantly for both concentrations of nitrous oxide (the MCA monitored in our healthy volunteers is representative of a large calibre vessel). We believe the differences in CBF and *V*tam measurements lend further support to suggested differences in behaviour between the small and large calibre vessels of the brain. However, with indirect measurements, we are unable to support this theory.

Autoregulation has to be intact for the effects of nitrous oxide on CBF to be self-limiting. In those patients with intracerebral pathology in whom it is partially or totally abolished, there is evidence to suggest that nitrous oxide has a marked deleterious effect on cerebral haemodynamics [6]. Until recently, there have been no studies relating the use of nitrous oxide to neurological outcome. Baughman and colleagues examined this, together with neurohistopathological outcome, in rats subjected to incomplete cerebral ischaemia and given nitrous oxide alone, isoflurane alone or both agents in combination [29]. They found that nitrous oxide attenuated the cerebral protective effect of isoflurane and, when given alone, was associated with the worst prognosis.

There is increasing interest in the pulsatility index as a reliable indicator of cerebral perfusion, and its potential as a continuous non-invasive monitor is considerable. Our results confirm the relationship of 1/PI to CBF: both demonstrated the plateau we have described. Although 1/PI was not shown to increase significantly with 30 % nitrous oxide (this we believe was probably a reflection of the small number of subjects in our study), the overall trend was the same.

In conclusion, we believe two important facts have emerged from our study: first, nitrous oxide increases CBF. Second, the effect of nitrous oxide reaches a plateau at approximately 30 %. We suggest that intact autoregulation is the most likely explanation for this latter observation. In light of this, the use of nitrous oxide must be considered very carefully in patients with cerebral pathology in whom autoregulation is impaired.

NEOSTIGMINE AND EDROPHONIUM ANTAGONISM OF MODERATE NEUROMUSCULAR BLOCK INDUCED BY PANCURONIUM OR TUBOCURARINE

G. D. SHORTEN, H. H. ALI AND N. G. GOUDSOUZIAN

SUMMARY

Edrophonium and neostigmine are anticholinesterase drugs used commonly to antagonize competitive neuromuscular block. Although it has a faster onset of action than neostigmine, edrophonium is unreliable when used to antagonize deep neuromuscular block. We have compared the antagonist characteristics of these two drugs when used to antagonize a moderate degree of pancuronium- or tubocurarine-induced neuromuscular block. Forty ASA I or II patients undergoing surgical procedures were allocated randomly to receive either pancuronium 70 μg kg^{-1} or tubocurarine 0.5 mg kg^{-1}, and to receive either edrophonium 0.5 mg kg^{-1} or neostigmine 0.05 mg kg^{-1}. Antagonism was attempted when the first response to train-of-four (TOF) stimulation recovered spontaneously to 25% of the control height. Neuromuscular function was monitored using the evoked integrated electromyogram of the first dorsal interosseous muscle of the hand. Adequate recovery was defined as the achievement of a TOF ratio of 0.70 or greater. Only seven of 20 patients who received edrophonium demonstrated adequate recovery 30 min after antagonism. Under the conditions described in this study, edrophonium 0.5 mg kg^{-1} was less effective as an antagonist than neostigmine 0.05 mg kg^{-1}. (Br. J. Anaesth. 1993; **70**: 160–162)

KEY WORDS

Antagonists, neuromuscular relaxants: edrophonium, neostigmine. Neuromuscular relaxants: pancuronium, tubocurarine.

The role of edrophonium in the antagonism of non-depolarizing neuromuscular block is uncertain. Its potential advantages include a faster onset of action (which, unlike neostigmine, makes it feasible to titrate dose to effect) and a lower requirement for anticholinergic drugs [1, 2]. In the presence of profound neuromuscular block (single twitch height < 10% of control height) these advantages appear to be offset by the inadequacy of the degree of recovery [3].

Intraoperative neuromuscular monitoring using a peripheral nerve stimulator is now widely practised and may be used reliably to differentiate between profound and moderate degrees of neuromuscular block. The effectiveness of edrophonium as an antagonist, when used at the lesser degree of neuromuscular block, is unclear. In order to examine this question, we attempted antagonism of a moderate degree of neuromuscular block (when the first response of TOF recovered spontaneously to 25% of the control height). Adequate antagonism was defined as the achievement of a train-of-four (TOF) ratio of 0.70 or greater. Our objective, therefore, was to compare edrophonium 0.5 mg kg^{-1} with neostigmine 0.05 mg kg^{-1} as antagonists of a moderate degree of neuromuscular block.

PATIENTS AND METHODS

After obtaining written informed consent and Institutional Ethics Committee approval, we studied 40 ASA I or II surgical patients undergoing elective surgery. Patients with neuromuscular disease or those receiving medication known to influence neuromuscular function were excluded.

Anaesthesia was induced with thiopentone 3–5 mg kg^{-1} and fentanyl 1–3 μg kg^{-1} and maintained with 66% nitrous oxide in oxygen, and increments of fentanyl, thiopentone, or both, as indicated clinically. Oral tracheal intubation was facilitated using pancuronium 70 μg kg^{-1} ($n = 20$) or tubocurarine 0.5 mg kg^{-1} ($n = 20$) according to random allocation.

The evoked integrated electromyogram (EMG) of the first dorsal interosseous muscle of the hand in response to supramaximal ulnar nerve TOF stimulation at 2 Hz was recorded and repeated once every 20 s using a Datex 221 NMT monitor. Two stimulating surface electrodes were placed over the ulnar nerve at the wrist and a sensing electrode placed over the belly of the first dorsal interosseous muscle with the reference electrode over the base of the proximal phalanx of the index finger. The ground electrode was placed at the wrist between the stimulating and recording electrodes. The monitored hand was immobilized in a fist-like position and enclosed in a plastic bag to minimize heat loss. An EMG control response was obtained after induction of anaesthesia when the eyelid reflex was abolished.

Correspondence to H. A. A.

When the first response of TOF recovered spontaneously to 25% of the control height, neuromuscular block was antagonized using either neostigmine 0.05 mg kg^{-1} or edrophonium 0.5 mg kg^{-1} according to random allocation.

The times from antagonism to recovery of first twitch height to 75% and 90% of the control value were measured, as were the TOF ratios corresponding to each of these levels of recovery. The times at which the TOF ratio reached 0.70 were also recorded if this occurred within 30 min of antagonism. Neuromuscular monitoring was discontinued either when the TOF ratio reached 0.70 or when 30 min had elapsed after antagonism.

The frequencies of adequate recovery were compared using two-tailed Fisher's exact test. Times to recovery of first twitch height to 75% and 90% of control and the corresponding TOF ratios were analysed using Friedman's analysis of variance (ANOVA on ranks) and Student's *t* test. $P < 0.05$ was taken to be significant.

RESULTS

The patient characteristics were similar in the four groups studied (table I). A Friedman ANOVA (ANOVA on ranks, table II) was performed to determine if differences existed between neuromuscular blockers, antagonists or interactions between the types of agent. This demonstrated a highly significant antagonist effect on the interval from antagonism to first twitch recovery to 75% and 90% ($P = 0.0001$ in each case). The rate of recovery of first twitch to 75% and 90% was significantly faster after endrophonium than after neostigmine ($P = 0.003$ and $P < 0.0001$ for 75% and 90% respectively) (table III) First twitch recovery to 75% of control occurred 1.3 min after antagonism with edrophonium and approximately 3.2 min after neostigmine. The corresponding intervals for recovery to 90% of control were approximately 1.5 min for edrophonium and 5 min for neostigmine.

TABLE I. *Patient characteristics (mean (range or* SD*))*

Group	Age (yr)	Sex (M:F)	Weight (kg)
Pancuronium–neostigmine	46.9 (22–79)	9:1	71.7 (11.6)
Pancuronium–edrophonium	46.3 (26–68)	8:2	67.7 (18.8)
Tubocurarine–neostigmine	35.4 (29–61)	7:3	68.3 (22.6)
Tubocurarine–edrophonium	44.2 (21–65)	9:1	70.3 (11.7)

TABLE II. *Results of Friedman ANOVA (ANOVA on ranks): the values shown represent the probability (P value) that a difference in the dependent variables is caused by the effect of a neuromuscular blocker, an antagonist, or their interaction. T75, T90 = Times from antagonism until first twitch response reached 75% and 90%, respectively, of control. TOF ratio at T1 75%, 90% = train-of-four ratio when first response to TOF stimulation is 75% and 90%, respectively, of control. Time to TOF ratio 0.70 = time from antagonism for train-of-four ratio to reach 0.70*

Dependent variable	Neuromuscular blocker	Antagonist	Interaction

at T1 75%	0.36	0.33	0.16
at T1 90%	0.10	0.44	0.01
Time to			
TOF ratio 0.70	0.17	0.14	0.38

TABLE III. *Mean (*SD*) times to single twitch recovery to 75% (T75) and 90% (T90)*

Group	T75	T90
Pancuronium–neostigmine	3.1 (1.9)	4.9 (2.0)
Pancuronium–edrophonium	1.3 (0.5)	1.5 (0.5)
Tubocurarine–neostigmine	3.2 (2.3)	5.3 (2.9)
Tubocurarine–edrophonium	1.3 (0.7)	1.7 (0.9)

TABLE IV. *Number of patients in each group in whom TOF ratio was greater than or equal to 0.70 30 min after antagonism*

Group	Total No. patients	No. with TOF ratio < 0.70
Pancuronium–neostigmine	10	10
Pancuronium–edrophonium	10	5
Tubocurarine–neostigmine	10	8
Tubocurarine–edrophonium	10	2
Neostigmine	20	18
Edrophonium	20	7

Irrespective of the neuromuscular blocking drug used, the frequency of adequate recovery was significantly greater after neostigmine than after edrophonium ($P = 0.0007$) (table IV). Only seven of the 20 patients who received edrophonium had TOF ratios greater than 0.70 at 30 min following antagonism (table IV). Two of 20 patients who received neostigmine exhibited inadequate antagonism with a TOF ratio less than 0.70 and both of these had received tubocurarine (table IV).

DISCUSSION

Our results indicate that, even when the depth of neuromuscular block is moderate and spontaneous recovery is well established, edrophonium 0.5 mg kg^{-1} is an unreliable antagonist of either pancuronium- or tubocurarine-induced neuromuscular block. Of 20 patients in whom antagonism was attempted using edrophonium, only seven demonstrated adequate recovery within 30 min. Eighteen of 20 patients in whom an equipotent dose of neostigmine was used demonstrated adequate recovery within 15 min. The insignificant *P* value (0.14), obtained using the ANOVA on ranks for antagonist effect on the time to reach a TOF ratio of 0.70 after antagonism is misleading. This occurred because patients who received edrophonium achieved TOF ratio = 0.70 either very rapidly or not at all (within the 30-min post-antagonism study period). Therefore, patients in the edrophonium group were ranked either very low or very high in terms of time to reach TOF ratio = 0.70, with a resultant cancelling effect.

Early investigations of edrophonium as an antagonist of non-depolarizing neuromuscular block indicated that it was unpredictable and that, because of its short duration of action, it was associated with recurarization [4]. When used to antagonize tubocurarine-induced neuromuscular block, edrophonium 10–20 mg initially produced a prompt increase in twitch height followed by a return of the recovery slope to pre-antagonism [5].

A subsequent investigation indicated that edrophonium, used in a larger bolus of 0.7 mg kg^{-1}, was an effective anticurare agent [6]. Independent work by Kopman [7] supported this finding, but emphasized the importance of the degree of neuromuscular block at which antagonism was attempted. It was concluded that, *provided four detectable responses to TOF stimulation were present*, edrophonium produced adequate and sustained recovery.

Reports followed to suggest the adequacy of edrophonium as an antagonist in a dose of 0.5 mg kg^{-1} or greater. Edrophonium 50–100 mg/70 kg was found to be effective in antagonizing pancuronium-induced neuromuscular block at 10 % recovery of muscle twitch [8]. At equiantagonistic doses, the duration of action of edrophonium was equal to that of neostigmine (0.5 mg kg^{-1} and 0.043 mg kg^{-1}, respectively) [1]. It was pointed out, however, that, as the dose–response curve of edrophonium was not parallel to those for neostigmine and pyridostimine, the relative potencies of the drugs would change with the degree of neuromuscular block at the time of administration. When neostigmine or edrophonium was used to antagonize atracurium-induced neuromuscular block of similar degree, adequate recovery (TOF ratio > 0.70) was demonstrable in all patients who received neostigmine 0.05 mg kg^{-1}, but in only 13 of 20 in whom edrophonium 0.5 mg kg^{-1} was used [9].

By 1986, it was apparent that edrophonium might be used successfully under certain circumstances only. Rupp and colleagues [10] compared edrophonium with neostigmine as antagonists of profound (single twitch $\leqslant 10\%$) and mild or moderate (single twitch $> 10\%$) neuromuscular block. These authors concluded that the dose equivalent to neostigmine 0.04 mg kg^{-1} was edrophonium 1.0 mg kg^{-1} for profound block and 0.5 mg kg^{-1} for mild or moderate block. The shortcomings of this work, however, have been noted previously, in particular the small doses of neuromuscular blockers used and the fact that adequacy of antagonism was determined as the point at which the single twitch recovered to 90 % of control [11]. The present study contradicts the findings of Rupp's groups that mild to moderate neuromuscular block was equally and effectively antagonized with both edrophonium 0.5 mg kg^{-1} and neostigmine 0.04 mg kg^{-1}. Although the dose of neostigmine in our study (50 µg kg^{-1}) was greater than that used by Rupp's group, we consider it unlikely that this difference accounts for the discrepancy in these results. We consider it more likely that the return of single twitch height to 90 % of control does not truly reflect adequate recovery.

Comparing edrophonium 0.5 mg kg^{-1} and neostigmine 0.04 mg kg^{-1} as antagonists of pancuronium-induced moderate neuromuscular block, Sanfilippo and colleagues [12] demonstrated that adequate antagonism using the former was inconsistent. However, these authors administered a smaller initial dose of pancuronium (0.05 mg kg^{-1}) after recovery from suxamethonium 1 mg kg^{-1}. Under these circumstances, a prolonged non-depolarizing block with pancuronium has been demonstrated [13]. We used a greater initial dose of pancuronium (70 µg kg^{-1}) to facilitate intubation in order to avoid this complicating factor.

Even when it is attempted to antagonize a moderate degree of neuromuscular block induced by pancuronium or tubocurarine, edrophonium 0.5 mg kg^{-1} is an inadequate antagonist. Thus we conclude that, in most situations, its relatively minor advantages are outweighed by this important factor.

TRACHEAL INTUBATION AFTER INDUCTION OF ANAESTHESIA WITH PROPOFOL, ALFENTANIL AND I.V. LIGNOCAINE

J. A. H. DAVIDSON AND J. A. GILLESPIE

SUMMARY

We have assessed tracheal intubating conditions in 60 ASA I or II patients after induction of anaesthesia with propofol 2.5 mg kg^{-1} and alfentanil 10 or 20 µg kg^{-1} with or without i.v. lignocaine 1 mg kg^{-1}. No neuromuscular blocking agents were administered. Patients were allocated randomly to four groups: group 1 = propofol–alfentanil 10 µg kg^{-1}; group 2 = propofol–alfentanil 10 µg kg^{-1}–lignocaine 1 mg kg^{-1}; group 3 = propofol–alfentanil 20 µg kg^{-1}; group 4 = propofol–alfentanil 20 µg kg^{-1}–lignocaine 1 mg kg^{-1}. Intubating conditions were assessed as acceptable or unacceptable on the basis of a scoring system dependent on ease of laryngoscopy, vocal cord position and coughing on insertion of the tracheal tube. Intubating conditions were acceptable in 20%, 73%, 73% and 93% of patients in groups 1–4, respectively. Intubating conditions were better and there was less coughing in the lignocaine group. (Br. J. Anaesth. 1993; **70**: 163–166)

KEY WORDS
Anaesthesia: intravenous. Intubation tracheal: technique.

Recent work has suggested that in premedicated patients an induction dose of propofol 2.5 mg kg^{-1} may provide adequate conditions for laryngoscopy and tracheal intubation without the need for neuromuscular blocking agents [1]. The efficacy of this single agent technique, however, has been debated [2], but in several individuals it is associated with sub-optimal conditions: undesirable haemodynamic responses, difficulty in seeing the larynx and intolerance of the tracheal tube.

It has been demonstrated that adjuvant agents, such as opioids, adrenergic blockers, and local anaesthetic agents, may suppress the cardiovascular response to laryngoscopy and tracheal intubation [3, 4] and improve tolerance of the tracheal tube. Although alfentanil and lignocaine have been shown to attenuate the cardiovascular response to intubation [5, 6], the effect of a combination of these drugs on intubating conditions remains poorly documented.

In this double-blind, randomized study, intubating conditions and haemodynamic response to intubation (in the absence of neuromuscular block) were assessed in patients induced with propofol 2.5 mg kg^{-1} and alfentanil 10 or 20 µg kg^{-1}. The effect of supplementing this regimen with i.v. lignocaine 1 mg kg^{-1} was evaluated.

PATIENTS AND METHODS

We studied 60 ASA I or II patients undergoing elective gynaecological surgery. Ethics Committee approval was obtained and each patient gave written informed consent. Patients whose physical characteristics suggested difficulties in intubation (Mallampati Class III) [7] and those who had a previously documented failed intubation were excluded from the study. All patients were premedicated with temazepam 20–30 mg approximately 1 h before anaesthesia. Patients were allocated randomly to one of four groups: group 1 = propofol 2.5 mg kg^{-1} and alfentanil 10 µg kg^{-1}; group 2 = propofol 2.5 mg kg^{-1}, alfentanil 10 µg kg^{-1} and i.v. lignocaine 1 mg kg^{-1}; group 3 = propofol 2.5 mg kg^{-1} and alfentanil 20 µg kg^{-1}; group 4 = propofol 2.5 mg kg^{-1}, alfentanil 20 µg kg^{-1} and i.v. lignocaine 1 mg kg^{-1}. Lignocaine and alfentanil were placed in 5-ml syringes and 0.9% saline was added to make a volume of 5 ml. Patients in groups 1 and 3 received saline 5 ml in place of lignocaine. Saline or lignocaine was administered 2 min and alfentanil 1 min before induction of anaesthesia with propofol. All injections were given over a period of 20 s. Laryngoscopy and intubation were attempted after loss of eyelash reflex (No. 3 Macintosh laryngoscope blade, 8.0-mm Portex tracheal tube). The study was performed in a double-blind fashion, the anaesthetist performing the intubation (J.A.H.D. or J.A.G.) being unaware of the group to which the patient had been allocated. Ease of intubation was assessed on the basis of the scoring system devised by Helbo-Hansen, Ravlo and Trap-Anderson [8]. Degree of coughing, position and movement of the vocal cords, and ease of laryngoscopy were estimated on a scale of 1–4 (table

TABLE I. *Intubating condition score*

	Score 1	 2	 3	 4
Laryngoscopy	Easy	Fair	Difficult	Impossible
Vocal cords	Open	Moving	Closing	Closed
Coughing	None	Slight	Moderate	Severe

TABLE II. *Patient data (mean (range or* SD*))*

	Group 1	Group 2	Group 3	Group 4
Age (yr)	32.4	29.7	30.9	31.87
	(24–46)	(24–38)	(24–40)	(25–38)
Weight (kg)	60.6	67.9	61.8	61.1
	(11.4)	(12.7)	(14.7)	(11.8)

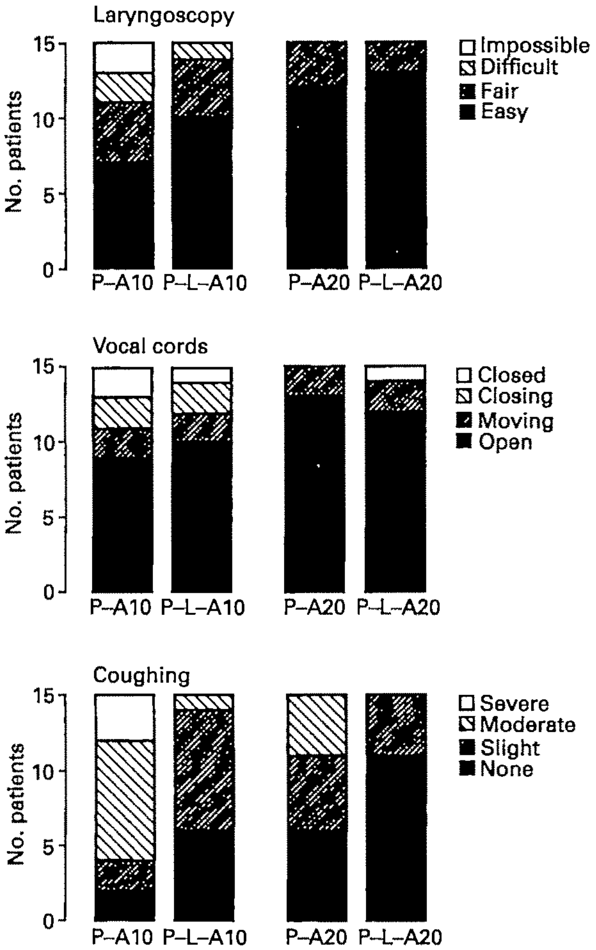

FIG. 1. Intubating condition score for laryngoscopy, vocal cords and coughing in patients from each group. P = Propofol; A10 = alfentanil 10 μg kg^{-1}; A20 = alfentanil 20 μg kg^{-1}; L = lignocaine.

I). Intubating conditions were judged acceptable when all scores were 2 or less. If any of the scores were 3 or 4, intubating conditions were judged unacceptable. Patients in whom intubation was impossible were given suxamethonium to optimize conditions.

After tracheal intubation, the lungs were ventilated with 67% nitrous oxide in oxygen 70 ml kg^{-1} min^{-1} (fresh gas flow) via a Mapleson D system, and after completion of the study period (2 min after intubation), inhalation agents were added to maintain anaesthesia.

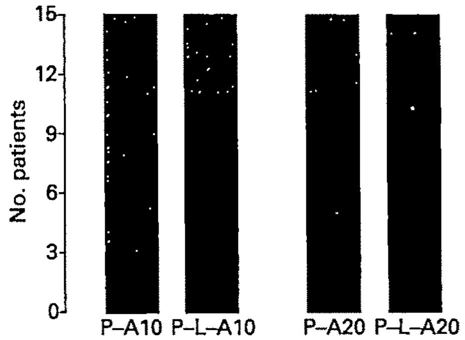

FIG. 2. Overall intubating conditions in patients from the four groups. All scores ≤ 2 = acceptable intubating conditions (■); any score > 2 = unacceptable intubating conditions (▨). P = Propofol; A10 = alfentanil 10 μg kg^{-1}; A20 = alfentanil 20 μg kg^{-1}; L = lignocaine.

Patients were monitored continuously by ECG and pulse oximetry. A baseline arterial pressure (Dinamap, Critikon) was measured before induction and was repeated immediately after both induction and intubation and thereafter at 1 and 2 min.

Statistics

The chi-square test and the Mann–Whitney *U* test were used for non-parametric data and the paired Student's *t* test and ANOVA for parametric data. The Bonferroni correction was used for inter- and intragroup comparisons. $P < 0.05$ was regarded as significant.

RESULTS

The four groups were comparable in age and weight (table II). There were no significant intergroup differences for baseline mean arterial pressure and heart rate. One patient commented spontaneously on tinnitus after injection of lignocaine. There was no other evidence of lignocaine toxicity.

Intubation was completed successfully in 56 of the 60 patients. In two patients in group 1, visualization of the larynx was impossible on laryngoscopy and in one patient from group 1 and one patient from group 2, the vocal cords were tightly closed, preventing intubation. After suxamethonium, intubation was achieved successfully in these four patients. Assessment of laryngoscopy, vocal cords and coughing are shown in figure 1. Vocal cord assessment was not greatly different between the four groups. Although ease of laryngoscopy improved with both the addition of i.v. lignocaine and the larger dose of alfentanil, the differences were not statistically significant. The incidence of coughing on insertion of the tracheal tube was reduced with lignocaine added to both the propofol–alfentanil 10 μg kg^{-1} ($P < 0.01$) and the propofol–alfentanil 20 μg kg^{-1} regimens.

The overall assessment of intubating conditions is shown in figure 2. Only three of 15 patients (20%) in group 1 were deemed to have satisfactory intubating conditions, compared with 11 of 15 patients (73%) in groups 2 and 3 and 14 of 15 patients (93%) in group 4. There was a statistically significant dif-

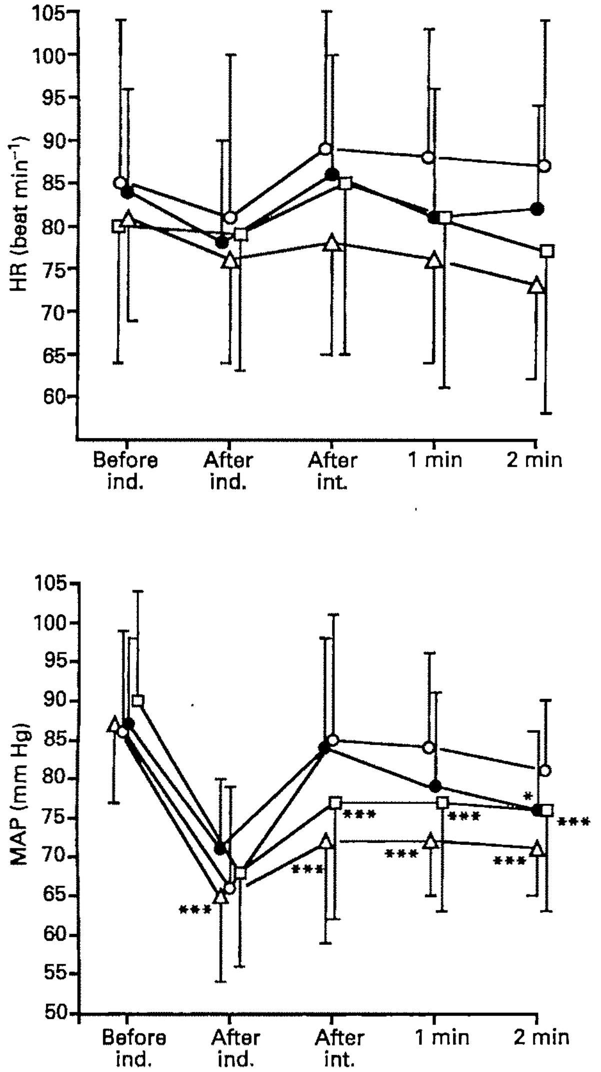

FIG. 3. Cardiovascular (heart rate (HR) and arterial pressure (MAP)) responses to laryngoscopy and intubation in the propofol–alfentanil 10 $\mu g\ kg^{-1}$ (○), propofol–alfentanil 10 $\mu g\ kg^{-1}$ with lignocaine (●), propofol–alfentanil 20 $\mu g\ kg^{-1}$ (□) and propofol–alfentanil 20 $\mu g\ kg^{-1}$ with lignocaine (△) groups. Within group statistically significant changes compared with the value before induction: *$P < 0.05$; ***$P < 0.001$. ind. = induction; int. = intubation.

ference ($P < 0.05$) between overall intubating conditions in group 1 (propofol–alfentanil 10 $\mu g\ kg^{-1}$) and group 3 (propofol–alfentanil 20 $\mu g\ kg^{-1}$). Addition of lignocaine to propofol–alfentanil 10 $\mu g\ kg^{-1}$ resulted in an improvement in intubating conditions ($P < 0.05$). Similarly, supplementing propofol–alfentanil 20 $\mu g\ kg^{-1}$ with lignocaine improved intubating conditions, although this did not achieve statistical significance.

Cardiovascular responses to induction and intubation are shown in figure 3. Heart rate decreased after induction and increased after intubation in all groups. However, none of the changes was statistically significant compared with baseline values. Similarly, mean arterial pressure decreased in all groups after induction ($P < 0.001$). However, there was an increase in all groups after intubation, but the mean arterial pressure remained depressed in groups 3 and 4 compared with pre-induction values ($P < 0.005$ and $P < 0.001$, respectively).

DISCUSSION

Several studies have concluded that intubation is possible without the use of neuromuscular blocking agents. Lewis demonstrated in 1948 that adequate conditions for intubation could be achieved using thiopentone alone [9]. McKeating and colleagues [10] found that, when no neuromuscular blocking drugs were given, laryngoscopy was possible significantly more often after propofol than after thiopentone. Conditions, however, are not always optimal. Keavney [1], using only propofol 2.5 mg kg^{-1}, reported satisfactory intubating conditions in 12 of 20 patients (60 %), whereas Saarnivaara and Klemola [2], using a similar regimen, reported that only five of 13 patients (38 %) had intubating conditions that were adequate. Even after administration of alfentanil 20 $\mu g\ kg^{-1}$ 30 s before induction, in only 10 of 15 patients (66 %) were intubating conditions deemed to have been adequate [2].

In this study, we have demonstrated that the use of i.v. lignocaine to supplement propofol–alfentanil anaesthesia improved intubating conditions. Lignocaine 1 mg kg^{-1} i.v., when administered 2 min before induction with propofol–alfentanil 10 $\mu g\ kg^{-1}$, increased the number of patients with acceptable intubating conditions from three of 15 (20 %) to 11 of 15 (79 %) ($P < 0.05$). The improvement in intubating conditions was largely caused by a reduction in the incidence and severity of coughing after insertion of the tracheal tube, although an improvement in the ease of laryngoscopy was also apparent.

There are many reports on the antitussive effects of i.v. lignocaine [11–13]. Lignocaine has also been shown to attenuate the increase in heart rate [13], arterial pressure [14] and intracranial pressure [15] associated with laryngoscopy and intubation. The mechanism whereby i.v. lignocaine suppresses the cough reflex is still unclear, but the efficacy has been shown to increase in a dose-dependent manner, and correlates well with plasma concentrations [13]. Yukioka and colleagues demonstrated that administration of lignocaine 2 mg kg^{-1} was effective in blocking the cough reflex during intubation in patients in whom anaesthesia was induced and maintained with nitrous oxide and halothane in oxygen, coughing being effectively eliminated by plasma concentrations of lignocaine in excess of 3 $\mu g\ ml^{-1}$ [13]. It was planned initially to use a 2-mg kg^{-1} dose of i.v. lignocaine in this study; however, after a small pilot study in which five of six patients complained spontaneously of tinnitus, circumoral paraesthesia and dizziness, the dose was reduced to 1 mg kg^{-1}. This dose significantly reduces the incidence of coughing [13] and, as we have demonstrated, was associated with minimal side effects.

It is likely that the antitussive effect of lignocaine is caused at least partially by an increase in the depth of general anaesthesia. Indeed, blood concentrations of 3–6 $\mu g\ ml^{-1}$ are known to potentiate the effects of nitrous oxide anaesthesia with a 10–28 % reduction in the minimum alveolar concentration (MAC) of halothane [16].

EFFECTS OF INTRADERMAL LIGNOCAINE AND MEPIVACAINE ON HUMAN CUTANEOUS CIRCULATION IN AREAS WITH HISTAMINE-INDUCED NEUROGENIC INFLAMMATION

H. FRUHSTORFER AND G. WAGENER

SUMMARY

The vasoconstrictive potencies of lignocaine and mepivacaine were studied in human skin. Lignocaine 0.5%, 0.25% mepivacaine (both plain and mixed with adrenaline or ornipressin), and saline (control) were injected intradermally into skin areas with enhanced perfusion (1% histamine prick). Flux was determined by scanning laser Doppler flowmetry and the size of any eventual pallor was measured. The artificially enhanced flux was increased further by saline, but not altered by the local anaesthetics. Mepivacaine produced a small pallor. Both vasoconstrictors reduced flux significantly and produced a larger pallor. We conclude that both local anaesthetics have only a mild constrictive effect on precapillary vessels. Mepivacaine has, additionally, a constrictor effect on the postcapillary vascular bed, causing pallor. An effective precapillary constriction which reduces the capillary clearance of both local anaesthetics can be achieved only by addition of a vasoconstrictor. (Br. J. Anaesth. 1993; **70**: 167–172)

KEY WORDS

Anaesthetics, local: lignocaine, mepivacaine, vasoactivity. Skin: dermal blood flow.

Most modern local anaesthetics appear to be vasodilatators in clinical concentrations and vasoconstrictor agents such as catecholamines or vasopressin derivatives are usually added. The same local anaesthetics in small concentrations, however, apparently constrict vessels [1].

The vasoactive properties of local anaesthetics have been examined by many different experimental approaches. Methods to estimate cutaneous circulation in human skin include visual inspection of colour changes [2–5], thermal clearance [6] and laser Doppler flowmetry [7, 8]. Results are generally inconsistent and difficult to interpret.

Although the skin is easily accessible for examination of vasoactivity of drugs, it presents several difficulties for the interpretation of the results. First, at rest, capillary perfusion of the skin is so low that vasoconstrictor effects are difficult to detect [8]. Furthermore, even a minute injury such as the insertion of a fine needle [7, 9] or the injection of a small quantity of saline [7, 9] produces a rapid and marked increase in blood flow within a radius of up to several centimetres. This is caused by release of vasoactive substances (peptides, histamine) from stimulated nociceptors and mastcells (neurogenic inflammation; see [10] for a review). Consequently, the injection of a vasoconstrictive agent produces both dilatation and constriction in unpredictable proportions. For example, the intracutaneous (i.c.) injection of ropivacaine in a concentration thought to cause vasoconstriction enhances cutaneous perfusion, although the flux increase is less pronounced than that caused by saline [7].

In an attempt to find a stable and reproducible condition in which vasoconstriction can be measured, cutaneous vasodilatation induced by local heating has been used [8]. In this condition, the s.c. injection of 0.5% lignocaine causes a significant reduction in cutaneous blood flow, which is reduced further if adrenaline or ornipressin is added [8]. However, this does not pertain during regional anaesthesia, in which tissue is not heated, but rather stimulated by mechanical trauma and chemical irritation. Therefore a stable neurogenic inflammation of the skin seems to be a more natural condition to test local anaesthetics.

We have examined the vasoactive properties of 0.5% lignocaine and 0.25% racemic mepivacaine in skin areas with neurogenic inflammation induced by histamine. In these concentrations, lignocaine is thought to have vasodilator and mepivacaine vasoconstrictor properties [11]. Both drugs were used plain and in combination with adrenaline or ornipressin, and they were compared with saline as control. The induced changes in cutaneous circulation were determined by scanning laser Doppler flowmetry [12] and by the measurement of pallor and flare areas.

SUBJECTS AND METHODS

The following drugs were used: saline (0.9% NaCl, Braun Melsungen); lignocaine (0.5% Xylocain, Astra); mepivacaine (0.5% Scandicain, Astra); ornipressin (Por 8, Sandoz); adrenaline (Suprarenin 1:1000, Hoechst); histamine (1% histamine hydro-

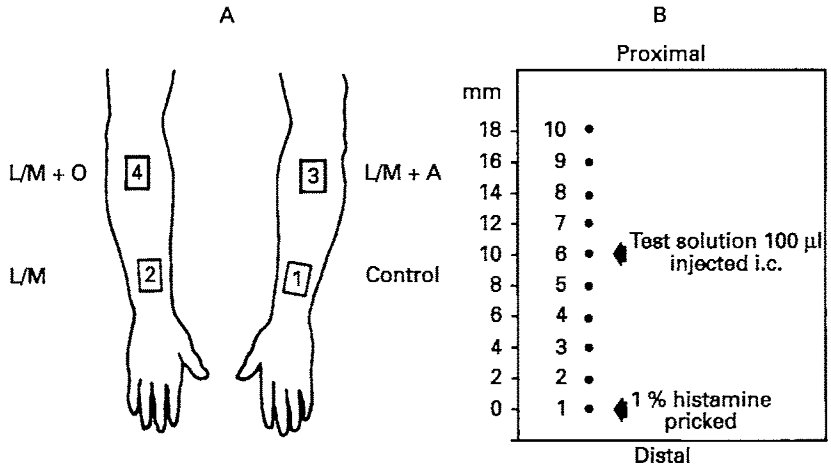

FIG. 1. A: Position of the four test areas on the dorsal forearms. Numbers give the order of testing. L = Lignocaine; M = mepivacaine. B: Position of the 10 measurement points and the points of histamine prick and of test solution injection. At each of the 10 points, flux was measured at a rate of 1 per 25 s. Each flux value represents the average of four consecutive measurements during 2 s.

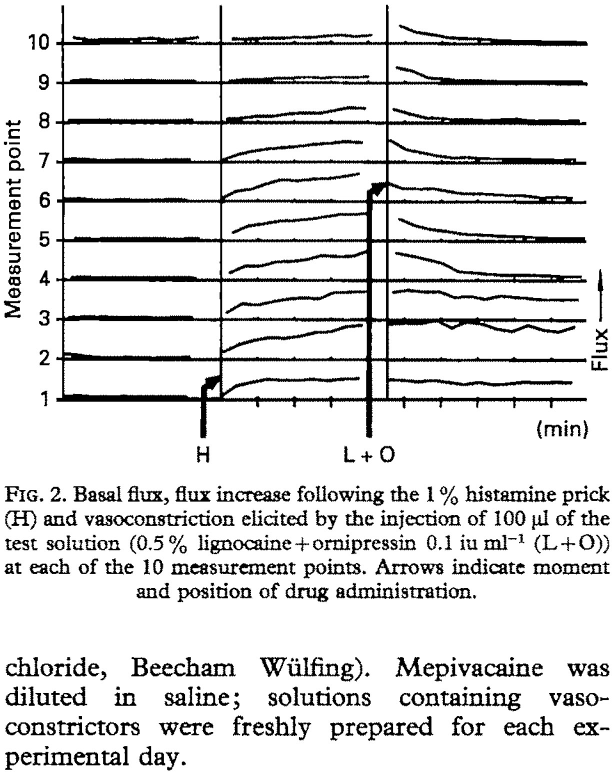

FIG. 2. Basal flux, flux increase following the 1 % histamine prick (H) and vasoconstriction elicited by the injection of 100 µl of the test solution (0.5 % lignocaine + ornipressin 0.1 iu ml^{-1} (L + O)) at each of the 10 measurement points. Arrows indicate moment and position of drug administration.

chloride, Beecham Wülfing). Mepivacaine was diluted in saline; solutions containing vasoconstrictors were freshly prepared for each experimental day.

We studied 24 healthy volunteers (10 male) (mean age 25.6 yr, range 22–32 yr) who had given informed consent. In 12 subjects, lignocaine was examined; this group received saline (control), plain 0.5 % lignocaine (L), 0.5 % lignocaine with adrenaline 5 µg ml^{-1} (L + A) and 0.5 % lignocaine with ornipressin 0.1 iu ml^{-1} (L + O). In the other group ($n = 12$), mepivacaine was examined: saline (control), plain 0.25 % mepivacaine (M), 0.25 % mepivacaine with adrenaline 5 µg ml^{-1} (M + A) and 0.25 % mepivacaine with ornipressin 0.1 iu ml^{-1} (M + O).

Neurogenic inflammation was elicited by pricking 1 % histamine into the skin. Cutaneous perfusion was monitored by a two-channel laser Doppler flowmeter (Moore Instruments MFD3) combined with an automatic scanning device [12]. The approximate area of flare was estimated by measuring its long and short axes and calculating the area of an ellipse. The outline of a pallor was transferred to transparent film and its area determined by weighing the cutting.

Before an experiment, four test areas were selected on both dorsal forearms (fig. 1A); the test areas were not randomized as, in this region, basal capillary perfusion and the response to histamine are comparable. The scanning device was fixed to the area by double adhesive tape and flux was measured at a rate of one per 25 s at each of 10 points 2 mm apart (fig. 1B). After baseline flux had been recorded for 3 min, histamine was pricked at point 1. Flux recording was continued for another 3 min to allow development of neurogenic inflammation. Then 100 µl of the test solution was injected i.c. with a 26-gauge needle at point 6 (fig. 2). The depth of the injection was selected carefully to be as shallow as possible, but deep enough to avoid the development of a pale papule. After the injection, the recording was continued for another 5 min, then the axes of the flare were measured and the size of any eventual pallor was transferred to transparent film. After another 5 min, the final size of the pallor was recorded. All flux data were collected continuously by computer.

After an experiment, basal flux values, maximal flux after histamine prick and maximal deviation from histamine flux during the 5 min after injection of the test substances were determined for each measurement point. Maximal flux changes elicited by the administration of histamine or the test solutions were expressed as per cent of basal flux (= 100 %). In addition, the latencies of 50 % maximal flux reduction were determined for the solutions containing additives. For statistical analysis, the flux values at measurement point 4 were selected, because at this point neurogenic inflammation and the vasoconstrictor effects of the drugs combine without being disturbed by the tissue pressure of the histamine weal or of the injection. For each group, differences between histamine-enhanced flux and drug-induced flux responses and the differences in the size of pallors were tested by the Wilcoxon signed rank test for paired replicates. In order to

maintain an overall 5 % level of significance, the limits within the single tests were adjusted according to Bonferroni–Holm.

RESULTS

In all subjects, histamine caused a rapid increase in cutaneous perfusion which, on average, was more than 10-fold baseline flux near the prick; at increasing distance from the prick, flux values decreased and reached about four times baseline at point 10 (figs 2–4). There were great interindividual variations in the reactivity to histamine. The average flare size was 6.94 (SD 2.54) cm^2 in group L and 7.22 (2.22) cm^2 in group M. In both groups, the injection of saline produced a further statistically significant increase in perfusion (figs 3, 4). The injection of plain lignocaine caused a slight increase in perfusion in 11 of the 12 test subjects; no colour changes of the skin around the injection occurred. Plain mepivacaine did not change perfusion between the histamine prick and the injection; in the periphery of neurogenic inflammation, 10 of the 12 subjects produced a small flux reduction. Nine subjects developed a distinct pallor around the mepivacaine injection (fig. 5). Both adrenaline and ornipressin, when added to the local anaesthetic, caused a decrease in skin perfusion (statistically significant for L+A, L+O and M+A) which reached baseline values around the injection (figs 3, 4). In both groups, the flux decrease tended to develop more rapidly with adrenaline than with ornipressin (fig. 6) and it was accompanied by a marked pallor. Five minutes after the injection, the pallor had reached almost its final size, which was the same for adrenaline and ornipressin, when added to lignocaine; however, when added to mepivacaine, ornipressin produced, in all cases, a smaller pallor (fig. 5). The pallor produced by plain mepivacaine was in all cases smaller than that elicited by the two vasoconstrictors.

DISCUSSION

Histamine-induced neurogenic inflammation of the skin has proved to be a good experimental method for studying vasoactive properties of local anaesthetics. It provides a stable condition of enhanced blood flow lasting up to 1 h and allows observation of both vasodilatation and vasoconstriction. The vascular effects of small quantities of local anaesthetics, when injected into the skin with artificially enhanced blood flow, result from three separate mechanisms: the initial mechanical trauma and chemical irritation stimulate nociceptors and cause additional vasodilatation; the local anaesthetic blocks sympathetic axons and reduces the thermoregulatory vasoconstrictor tone (true for hands and feet); the local anaesthetic has intrinsic effects on vascular smooth muscle, either direct or through mediators.

Assuming that the injection of saline causes only neurogenic inflammation, a local anaesthetic without intrinsic vasoactivity should cause a comparable increase in blood flow. In this study, 0.5 % lignocaine increased flux less than saline and 0.25 %

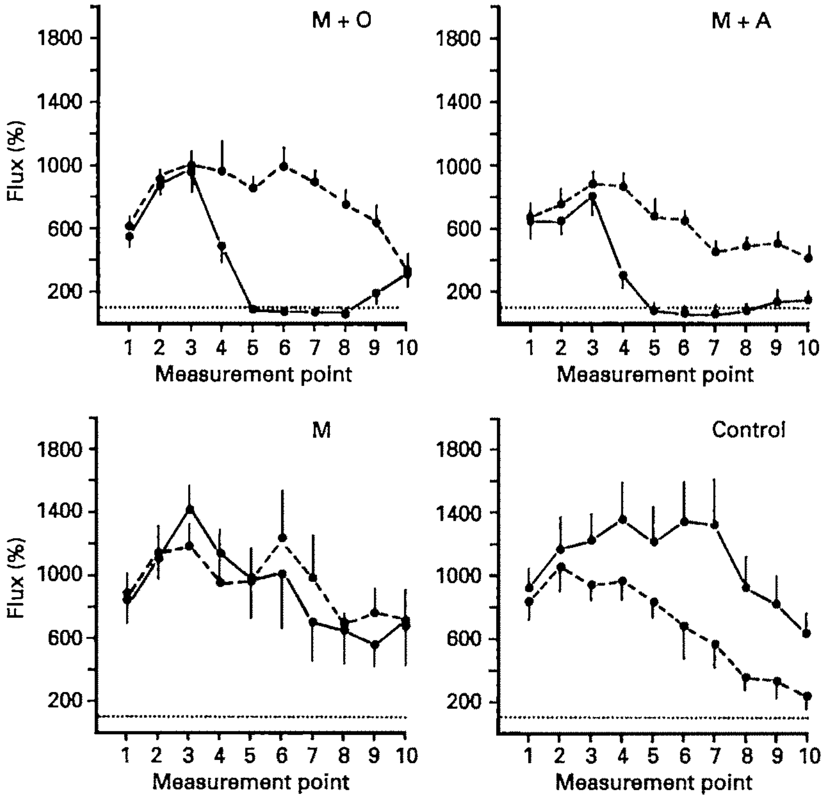

FIG. 4. Mepivacaine results. Average maximal flux following histamine prick (——) and average maximal deviation from histamine flux during the 5 min following the injection of the test solutions (——). mepivacaine even tended to reduce flux in the periphery of neurogenic inflammation. This indicates that both local anaesthetics in the concentrations used have a mild intrinsic constrictor effect on the precapillary side of human skin circulation. A decrease in cutaneous blood flow caused by s.c. 0.5 % lignocaine has been observed earlier in a study with heat-induced vasodilatation [8]. Mesnil du Rochemont and Hensel [6], using a thermal clearance method with intradermal injection of 1 % lignocaine or 1 % mepivacaine, found a reduction in flow following an initial increase of about 20 min duration (probably the effect of the injection trauma). Other studies using laser Doppler flowmetry found, in comparison with saline, larger flux increases with 1 % lignocaine [7, 11]; conversely 0.5 % mepivacaine produced smaller flux increases [11].

Although we found that 0.5 % lignocaine and 0.25 % mepivacaine did not alter artificially enhanced perfusion to a significant extent, both drugs differed in one important aspect: in the majority of cases, mepivacaine produced a small pallor whereas lignocaine did not. This is puzzling, because flux in the pallor area was still considerably enhanced and it was far from the baseline values which were reached when vasoconstrictors were

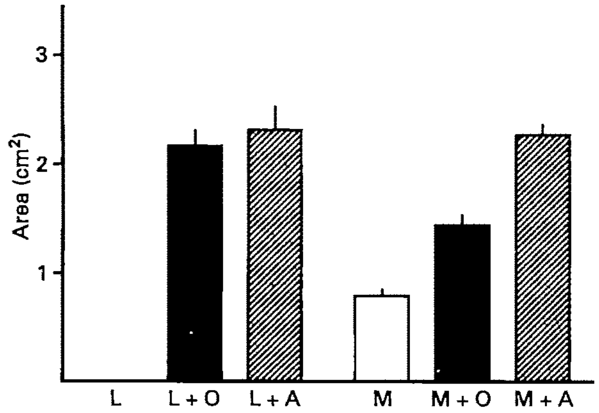

FIG. 5. Average area of pallors 10 min after the injection of the test solutions. Bars give SE to one side. L = Lignocaine; O = ornipressin; A = adrenaline; M = mepivacaine.

added. The dissociation between flux and colour is probably caused by the fact that the flowmeter measures the volume of blood per minute passing through the vertically arranged capillary loops, whereas skin colour is determined mainly by the volume of blood present within the deeper horizontal networks of the venous plexus. If a drug has a differential effect on precapillary and postcapillary vessels, a large flux in a pale skin could result. Therefore it is possible that 0.25% mepivacaine has a stronger constrictive effect on venules and veins than on arterioles and precapillary sphincters. When a small concentration of mepivacaine is injected into untreated skin, trauma-elicited neurogenic inflammation overcomes the mild constrictor action on precapillary vessels, leading to a flux increase [6, 11]. Simultaneously, in the postcapillary vascular bed, vasoconstriction prevails; the resulting pallor has been observed in several studies [3, 5]. In this study, no pallor was observed with 0.5% lignocaine, indicating that the constrictor effect on the postcapillary vessels was less marked. A differential effect on the arterial and venous vascular beds has also been observed when lignocaine and mepivacaine were infused into the brachial artery of human volunteers [13]: no direct effects on vascular resistance occurred, whereas venous tone was increased markedly. The differential effects of mepivacaine on arterial and venous vascular beds could be explained by the existence of two different routes of action. When injected in small concentrations into the extracellular space, the local anaesthetic penetrates the adventitia and has a direct constrictor effect on vascular smooth muscle. At the same time, the local anaesthetic is leaking through the capillary walls and drains away through venules and veins of the venular plexus. There, it could exert an additional indirect effect on venous smooth muscle mediated by the endothelium; it could either stimulate the release of endothelins or inhibit the release of endothelium-derived relaxing factor (EDRF). In man, the i.a. injection of an inhibitor of EDRF synthesis reduces arterial flow [14], but the i.v. injection does not by itself have a venoconstrictor effect [15]. In contrast, the intradermal injection of endothelin 1 causes a reduction in cutaneous perfusion, together with a small pallor [16]. Therefore, it could be that mepivacaine stimulates the endothelium to release endothelins. However, the absence of an increase in vascular resistance during i.a. infusion of mepivacaine when the sympathetic system is blocked [13] does not support a simple endothelium-mediated action of local anaesthetics.

When added to 0.5% lignocaine, both adrenaline and ornipressin caused a rapid decrease in flux to baseline values and they produced a pallor of comparable size. In combination with 0.25% mepivacaine, both vasoconstrictors produced a similar rapid flux decrease; ornipressin, however, produced a significantly smaller pallor. A similar difference could not be seen in the amplitude of the spatial extent of flux reduction (compare figures 3 and 4). Thus we conclude that mepivacaine antagonizes the action of ornipressin mainly in the postcapillary bed. The existence of an antagonism between various local anaesthetics and vasoconstrictors, including felypressin, has been observed in several studies [17, 18].

The ratio between dilator and constrictor effects on precapillary vessels may be different in other vascular beds in which nociceptor density and vasoactivity of local anaesthetics may differ. In the extradural space of the dog, plain 2% lignocaine causes a marked depression in spinal blood flow (microsphere flowmetry [19]), whilst in man the addition of adrenaline significantly reduces the leakage of the drug into the circulation and prolongs anaesthesia [20].

The present data give further support to the view of Covino [21] that vasoconstrictive and anaesthetic potency of a local anaesthetic are unrelated.

ANAESTHESIA AFFECTS PLASMA CONCENTRATIONS OF VASOPRESSIN, VON WILLEBRAND FACTOR AND COAGULATION FACTOR VIII IN CARDIAC SURGICAL PATIENTS

A. KUITUNEN, M. HYNYNEN, M. SALMENPERÄ, V. RASI, A. JÄRVINEN, M. SCHEININ, P. J. NEUVONEN AND F. FYHRQUIST

SUMMARY

Operative stress may affect haemostatic mechanisms through hormonal systems. As the endocrine stress response to surgery may be modulated by anaesthesia, we have altered stress hormone concentrations by using either opioid or inhalation based anaesthesia to study haemostatic mechanisms in cardiac surgical patients. Thirty patients undergoing coronary artery surgery were allocated randomly to receive fentanyl (non-stress group) or enflurane (stress group) as the main anaesthetic agent. After cardiopulmonary bypass (CPB), plasma arginine vasopressin (AVP) concentrations were significantly ($P < 0.001$) greater in the stress group (81.8 (46.9–142.9) pg ml^{-1}, mean with 95% confidence limits) than in the non-stress group (5.8 (3.3–10.2) pg ml^{-1}). Plasma noradrenaline and adrenaline concentrations increased similarly in both groups after CPB. Plasma concentrations of both von Willebrand factor (stress: 1.56 (1.33–1.79) iu ml^{-1}; non-stress: 1.00 (0.76–1.25) iu ml^{-1}) and coagulation factor VIII: C (stress 1.15 (0.87–1.44) iu ml^{-1}; non-stress: 0.69 (0.55–0.80) iu ml^{-1}) were significantly ($P < 0.01$) greater in the stress group than in the non-stress group after CPB. The results indicate that there is a temporal relationship between the increased plasma concentrations of AVP and von Willebrand factor and factor VIII: C. It is not clear if this indicates a causal relationship. However, variable stress control by anaesthesia may modify haemostasis in cardiac surgical patients. (Br. J. Anaesth. 1993; **70**: 173–180)

KEY WORDS

Blood: coagulation. Hormones: vasopressin. Surgery: cardiopulmonary bypass.

The endocrine response to surgery is characterized by increased plasma concentrations of stress-related hormones [1]. This response is especially pronounced during cardiopulmonary bypass (CPB) in patients undergoing cardiac surgery [2, 3]. Anaesthesia with large doses of opioids attenuates but does not abolish the stress response to cardiac surgery [4–6], while inhalation anaesthesia in small to moderate inspiratory concentrations is less effective [7–9].

Surgical stress activates the fibrinolytic system and increases plasma concentrations of coagulation factors with an increase in plasma arginine vasopressin (AVP) concentration [10, 11]. This suggests a possible causal relationship between stress hormones and regulation of haemostasis. Administration of exogenous adrenaline or vasopressin in large physiological concentrations induces increases in plasma concentrations of von Willebrand factor (vWF) and factor VIII: C and activates the fibrinolytic system in healthy volunteers [12–15].

Because various hormones seem to be involved in haemostatic regulation, we posed the hypothesis that the endocrine response to cardiac surgery might affect haemostasis. Therefore, we measured plasma concentrations of AVP, catecholamines and coagulation factor in patients undergoing coronary artery bypass grafting (CABG). Anaesthesia was designed to blunt the endocrine response to surgery in one group of patients, while a second group (stress group) was anaesthetized with a combination of anaesthetics thought not to abolish effectively the hormonal changes.

PATIENTS AND METHODS

The study was approved by the Hospital Ethics Committee. Patients with a history of previous cardiac surgery or coagulation disorder or those who had received coumarin anticoagulants, heparin or acetylsalicylic acid within 5 days before surgery were not entered in the study. Written informed consent was obtained from 34 patients undergoing elective primary CABG.

Anaesthesia

Patients were premedicated with lorazepam 0.06 mg kg^{-1} i.m. 2 h before induction of anaesthesia. The regular oral cardiovascular medication of the patients was given with the premedication. Consecutive patients were allocated randomly to one of two groups. The operating surgeon did not know to which group the patient belonged.

In the *non-stress group*, anaesthesia was induced with fentanyl 50 µg kg^{-1}, diazepam 0.3 mg kg^{-1} and pancuronium 0.1 mg kg^{-1}. A continuous infusion of fentanyl was started immediately after induction of anaesthesia, at a rate of 0.3 µg kg^{-1} min^{-1} until the start of CPB and thereafter 0.15 µg kg^{-1} min^{-1} until the end of operation. When required, enflurane was administered to keep the systolic arterial pressure (SAP) less than 150 mm Hg during the prebypass period. Ephedrine, in 2.5–5 mg increments, was given to maintain SAP greater than 80 mm Hg. During CPB, mean arterial pressure was maintained between 30 and 80 mm Hg by giving either phenylephrine, in 100–200 µg increments, or by adding enflurane to the fresh gas flow of the oxygenator. After CPB, enflurane was administered when SAP was greater than 130 mm Hg.

In the *stress group*, anaesthesia was induced with thiopentone 2–4 mg kg^{-1}, fentanyl 5 µg kg^{-1} and pancuronium 0.1 mg kg^{-1}. Thereafter, anaesthesia was maintained with enflurane. Enflurane was administered according to the same arterial pressure limits as in the fentanyl group before and during CPB. However, enflurane was given in inspiratory concentrations of at least 0.2 vol % to all patients in the enflurane group before and during CPB. After CPB, enflurane was administered as soon as SAP exceeded 90 mm Hg, if at the same time cardiac index was greater than 2.4 litre min^{-1} m^{-2} and there were no arrhythmias.

Diazepam 0.3 mg kg^{-1} was administered during CPB to all patients in both groups. After operation, the patients were considered to be awake when they could give correct responses to two questions by moving the head or limbs. After CPB, dopamine and nitroglycerine infusions were given in both groups according to clinical criteria.

Cardiopulmonary bypass

During CPB, non-pulsatile flow and membrane oxygenation (Capiox, Terumo Corporation, Tokyo, Japan) were used. The extracorporeal circuit was primed with 2000 ml of Ringer's acetate solution. The patients were subjected to moderate systemic hypothermia (nasopharyngeal temperature 28–30 °C). The pump flow was maintained at 2.4 litre min^{-1} m^{-2} during cooling and rewarming, and at 1.6 litre min^{-1} m^{-2} during hypothermia. Topical myocardial cooling, together with intermittent cold potassium cardioplegia solution, were used for myocardial protection. PCV was maintained greater than 20% during CPB by giving packed red cells. Administration of heparin and protamine was based on the individual heparin dose-activated coagulation time–response curves.

Fluid therapy

After induction of anaesthesia, one unit of blood was withdrawn from the patient and replaced with 1000 ml of Ringer's acetate solution. This autologous blood unit was given back to the patient after the available residual oxygenator perfusate had been returned after CPB. An additional dose of protamine 25 mg was given for each 500 ml of this residual oxygenator perfusate. Postoperative PCV was maintained at approximately 30% by giving packed red cells and Ringer's acetate solution as required. Blood loss and total haemoglobin loss through the chest tubes were measured from sternal closure until the first morning after operation.

Laboratory analyses

Blood samples for laboratory analyses were collected into plastic syringes via a radial artery cannula. A slow saline infusion containing no heparin was used to maintain the patency of the cannula. Samples were taken at the following times: before operation after induction of anaesthesia; 15 min after the end of CPB; 2 h after CPB; 5.5 h after CPB; 16 h after CPB. An additional sample for measurement of plasma AVP was also obtained during CPB at maximal hypothermia. Plasma samples were frozen (−70 °C) until the assay of hormones and coagulation factors. Protamine was given before the second sample. The autologous blood unit and residual oxygenator perfusate were returned to the patient between the second and third samples.

Plasma AVP concentration was measured using a previously described radioimmunoassay method [16] with an intra-assay coefficient of variation of 8% and an inter-assay coefficient of variation of 14%. Plasma catecholamine concentrations (noradrenaline and adrenaline) were measured using high pressure liquid chromatography with coulometric electrochemical detection (HPLC-EC), as reported previously [17]. The intra-assay coefficient of variation was 2% and the inter-assay coefficient of variation was 3%.

PCV and platelet count in whole blood were determined using a Sysmex Analyzer (Toa Medical Electronics, Hamburg, Germany). Platelet adhesion was studied by measuring platelet retention on glass beads [18]. For the measurement, arterial blood was drawn through Adeplat S column at a constant flow rate using a Adeplat pump (Semmelweiss, Milano, Italy). After the first 2 ml of the effluent was discarded, platelet count in the third 1 ml was measured and subtracted from that in an aliquot of unfiltered blood. The difference in platelet counts (glass bead retention) was calculated in per cent of platelet count in the unfiltered blood and expressed as platelet adhesion. Template bleeding time determination (BT) was performed on the volar surface of the forearm with Simplate II device (General Diagnostics, Organon Teknika, Turnout, Belgium). Plasma β-thromboglobulin assay (β-TG) was performed using a method described previously [19].

Serum total protein concentration, plasma fibrinogen, activated partial thromboplastin time (APTT) and prothrombin time (PT) were determined using standard techniques. von Willebrand factor antigen (vWF) was assayed by immunoelectrophoresis [20]. Factor VIII procoagulant activity (factor VIII:C) was assayed with a one-stage kaolin–cephalin time method utilizing factor VIII:C-deficient plasma as a substrate [21]. The factor VIII:C-deficient plasma was obtained from a patient with severe haemophilia A (factor VIII:C < 0.01 iu ml^{-1}). Factor V was assayed by one-stage prothrombin time technique [22]. The reference plasma for the determination of these coagulation factors was citrated plasma pooled from 20 healthy blood donors in Finnish Red Cross Blood Transfusion Service. Thromboelastograph (TEG) tracings (Hellige Company, Freiburg, Germany) were obtained from citrated whole blood. Coagulation was initiated by adding calcium chloride to the cuvettes. TEG tracings were analysed by measuring reaction time (R), coagulation time (R+K), clot formation (α-angle) and maximum amplitude [23].

Statistical analyses

Analysis of variance (ANOVA) for repeated measurements was first applied for statistical comparisons within and between the groups. For statistical significance after ANOVA, the means were compared between and within the groups with Sheffé's F test. Within groups, the values were compared with the value obtained after the induction of anaesthesia. The values between the groups were compared at each sample time. Log-transformation was applied to hormone data before statistical analyses because of skewed data. Two-tailed Fisher's exact test was applied to compare data of quantal nature. The number of internal mammary artery grafts (one or two) was used as a covariate in the analysis of covariance for comparisons of blood loss and total haemoglobin loss between the groups. $P < 0.05$ was considered statistically significant. Results are given as the arithmetic mean with SEM or 95% confidence limits, with the exception of the hormone results, which are presented as the geometric mean with 95% confidence limits.

RESULTS

Four of the 34 patients were excluded from the study. One of these had been allocated to the non-stress group. She had cardiac failure after operation and died soon after the operation. Three excluded patients had been allocated to the stress group. One had cardiac failure after operation and had to be treated with adrenaline. Two excluded patients required re-operation because of postoperative bleeding; the bleeding site was identified clearly in both. The haemostatic variables of these excluded patients did not differ from those of the remaining patients.

The final study groups were comparable in preoperative characteristics (table I). There was a slightly greater proportion of male patients in the non-stress group; mean weight was slightly larger in the stress group. However, there was no significant difference between the groups in weight or body mass index (wt ht^{-2}). In spite of the randomization, the number of patients with two internal mammary artery grafts was not similar in the groups (10 patients in the non-stress group *vs* three patients in the stress group; $P = 0.025$). All other intraoperative variables were comparable (table I). The preoperative values of the coagulation variables were also similar in the groups (table II). Awakening occurred significantly earlier in the stress group than in the non-stress group (87 (14) min *vs* 321 (102) min after the end of surgery; $P < 0.001$).

Plasma concentration of AVP did not differ between the groups immediately after induction of anaesthesia (fig. 1), but the AVP concentration was greater during CPB in the stress group than in the non-stress group (92.0 (50.7–133.2) pg ml^{-1} *vs* 8.5 (5.1–11.9) pg ml^{-1}; $P < 0.001$) (data not shown in fig. 1). There was a significant difference between the groups immediately after CPB, because plasma AVP concentration increased 20-fold from the value after induction in the stress group (fig. 1). The plasma concentration of AVP was significantly greater in the stress group than in the non-stress group at 2 h after CPB also. Until 5.5 h after CPB, plasma AVP concentration had increased also in the non-stress group, and there was no significant difference between the groups. On the first morning after operation, plasma AVP concentration had returned to the value after induction in both groups. Although there was a slightly greater proportion of females in the stress group, there was no difference in the AVP values between the sexes in the stress group.

Plasma concentrations of adrenaline and noradrenaline increased significantly in both groups immediately after CPB and remained increased until the end of the study. There was no significant difference between the groups at any stage (fig. 1).

PCV, serum total protein and platelet count decreased significantly after CPB in both groups (table II). There were no significant differences between the groups in PCV and serum concentration of total protein at any stages of the study, but platelet count was greater in the stress group 2 h and 5.5 h after CPB and on the first morning after operation. The decrease in platelet adhesion was significant in the non-stress group immediately after CPB, but this decrease was not significantly different from that observed in the stress group. Platelet adhesion recovered within 2 h after CPB and remained recovered for the rest of the study in both groups (table II). Plasma concentration of β-thromboglobulin increased significantly immediately after CPB in both groups, but had returned to the post-induction value until the first morning after operation. The bleeding time was significantly prolonged 2 h and 5.5 h after CPB in both groups. There was no significant difference between the groups in plasma concentration β-thromboglobulin or bleeding time at any stage of the study (table II).

Plasma concentration of factor VIII:C did not change significantly in the two groups immediately after CPB (fig. 2) but, because of a slight increase in the stress group and a slight decrease in the non-stress group, a significant difference in factor VIII:C concentration occurred between groups immediately after CPB. During the later course of the study, plasma concentration of factor VIII:C increased in both groups. Factor VIII:C concentration was increased significantly more in the stress group 2 h after CPB. However, 5.5 h after CPB and on the first morning after operation there was no difference between the groups. A similar course of changes was observed in von Willebrand factor. On the first morning after operation vWF concentration increased nearly two-fold in both groups compared with the postinduction values (fig. 2).

In both groups, plasma fibrinogen concentration decreased significantly after CPB, but returned to

TABLE III. *Cumulative blood loss and total haemoglobin loss during the postoperative period (mean (SEM))*

	Non-stress group	Stress group
Blood loss (ml)	1034 (83)	828 (41)
Haemoglobin loss (g)	55 (7)	37 (3)

the preoperative value until the first morning after operation (table II). Factor V concentration declined significantly immediately after CPB in both groups, but returned to control values thereafter. However, on the first morning after operation, factor V concentration was significantly greater in the stress group. APTT values were slightly but significantly prolonged 15 min after CPB in both groups, but thereafter APTT values did not differ from the values after induction. PT values decreased from baseline during the whole study period. There was no significant difference between the groups in either APTT or PT. There were also no significant differences in any TEG parameter between the groups. TEG reaction time was significantly decreased from the value after induction on the first morning after operation in the non-stress group. TEG R+K time decreased significantly from postinduction values on the first morning after operation in both groups. Compared with the value after induction, TEG α-angle decreased significantly 15 min after CPB and increased significantly on the morning after operation in the stress group. The maximal amplitude of the TEG tracing decreased significantly 0.25 h and 2 h after CPB in the stress group.

Postoperative blood loss and total haemoglobin loss were significantly smaller ($P = 0.0342$ and 0.0224, respectively) in the stress group than in the non-stress group. After the number of internal mammary artery grafts was used as a covariate in the analysis of covariance, there were no statistically significant differences in blood loss and total haemoglobin loss between the groups ($P = 0.162$ and 0.222, respectively).

DISCUSSION

The present study confirmed our earlier finding that fentanyl, administered continuously in a large dose and supplemented with other anaesthetics, abolished the vasopressin response to cardiac surgery for as long as the opioid was infused [6]. However, this anaesthetic method is not totally "stress free", because similar catecholamine responses were noticed in both groups immediately after CPB. In contrast, and as expected, the enflurane-based anaesthetic method did not prevent the endocrine response to surgery. The increase in plasma concentration of AVP in the enflurane-anaesthetized patients (stress group) after CPB and thereafter and in the fentanyl-anaesthetized patients (non-stress group) after operation was associated temporally with an increase in plasma concentrations of von Willebrand factor and factor VIII. A similar relationship was not observed with plasma concentrations of catecholamines and the coagulation factors. These findings suggest that the stress-related increase in plasma concentration of AVP, or some other stress factors not identified in this study (but not catecholamines), may affect haemostasis in cardiac surgical patients after bypass.

Marked increases in plasma concentrations of numerous stress-related hormones, such as cortisol, AVP, noradrenaline and adrenaline, have been reported in association with cardiac surgery. Cardiopulmonary bypass seems to be a potent trigger to increase the concentrations of these hormones [2, 3]. The hormonal responses to CPB have been attenuated with the administrations of both i.v. [6] and volatile [24] anaesthetics. In our stress group, the anaesthetic (enflurane) concentration was adjusted according to the arterial pressure response, whilst the opioid was given in a fixed dose. Thus the level of anaesthesia might occasionally have been lighter in the volatile anaesthetic group. Therefore, our results do not allow us to grade one anaesthetic technique as superior to the other as far as suppression of the endocrine response to cardiac surgery is concerned.

We found that our fentanyl technique attenuated the vasopressin response to CPB, but did not abolish the catecholamine response. The inhibitory effect of fentanyl on the stress response seems to be mediated (directly or indirectly) via the hypothalamus [25]. This effect of fentanyl decreases the AVP release. The lack of effect of high-dose fentanyl on the sympathoadrenal response to CPB is in agreement with the observations of others [26, 27].

AVP acts as an antidiuretic hormone at plasma concentrations of a few pg ml^{-1}. However, under certain conditions such as surgery, considerably greater plasma AVP concentrations may prevail [10, 11, 28, 29]. These very large concentrations, known to induce vasocontriction, are associated with increases in plasma concentrations of factor VIII and vWF [10, 11]. Such a relationship existed also in our patients. Observations in studies using infusion of exogenous AVP to man suggest that there is a threshold plasma AVP concentration of 20–25 pg ml^{-1} at which an increase in plasma concentration of factor VIII occurs [14, 15]. Our results agree with this suggestion, as a significant difference in plasma concentrations of vWF and factor VIII:C between the groups existed after CPB until the mean plasma concentration of AVP had increased to more than 20 pg ml^{-1}. Our observations support the hypothesis that AVP has a physiological role in the acute regulation of haemostasis in surgical patients [30]. Increased catecholamine release does not seem to play a determinant role in the acute regulation of haemostasis. During colonoscopy, plasma concentrations of factor VIII:C and vWF increased with an increase in plasma concentration of AVP, while plasma catecholamine concentrations remained unchanged [29]. In our study, there was no difference in catecholamine concentrations between the groups.

Large molecular weight multimers of vWF act as a glue to overcome high shear forces between circulating platelets and collagen exposed by endothelial injury. Loss of glycoprotein Ib receptors which bind vWF to platelet surfaces may be an important part of acquired platelet dysfunction induced by CPB [31]. Clinical studies suggest that increases in concentrations of the adhesive agonist, vWF, to greater than those known to be critical for adequate haemostasis in non-cardiac surgery, may improve haemostasis after CPB [32, 33]. Although plasma concentrations of vWF did not decline to less than prebypass values, there was a difference in the plasma vWF concentration between the two groups and this may have a potential to cause a difference in haemostasis.

We did not observe significant differences between the groups in clotting times and coagulation factors other than factor VIII:C and vWF. However, we observed a greater platelet count in the stress group from 2 h after CPB until the first morning after operation. This finding is consistent with a previous report that stress (exercise-induced) produced a transient thrombocytosis via an effect on the spleen [34]. However, when we compared changes from the baseline values of platelet count between our two groups, there was no difference.

The blood loss and total haemoglobin loss measured after operation were significantly smaller in the stress group. However, the significant difference in the number of internal mammary artery grafts between groups may have affected this. It has been shown that the use of bilateral internal mammary artery grafts in CABG increases requirements for blood transfusion compared with one graft only [35]. To assess this, we used the number of these grafts as a covariate in the analysis of the data. With this procedure, there was no statistically significant difference in blood loss and haemoglobin loss between the groups. In order to reach statistical significance for the observed difference in blood loss or total haemoglobin loss between the groups, the sample size should have been about 100 patients with a statistical power of 0.80 and a significance level of 0.05. Thus the implications of the effects of anaesthesia on plasma AVP and coagulation factor concentrations on clinical haemostasis will require investigation in a much larger study.

The choice of the anaesthetic technique in patients undergoing CABG does not seem to affect postoperative cardiac complications and overall outcome [36, 37]. However, the method used to control surgical stress may contribute to the acquired haemostatic defect after CPB, by affecting the plasma concentrations of haemostatic factors.

ACKNOWLEDGEMENTS

We thank Jussi Heinonen, M.D. and Gunnar Myllylä, M.D. for their critical review of the manuscript. We thank Elina Vahtera, PHIL.LIC., Ms Päivi Aho, Mrs Mailis Himberg and the personnel in the Laboratory of Haemostasis at the Finnish Red Cross Transfusion Service for their assistance. The study was supported by grants from the Paulo Foundation, the Instrumentarium Foundation and Helsinki University Central Hospital.

EFFECTS OF MIDAZOLAM AND FLUNITRAZEPAM ON THE RELEASE OF DOPAMINE FROM RAT STRIATUM MEASURED BY *IN VIVO* MICRODIALYSIS

K. TAKADA, T. MURAI, T. KANAYAMA AND N. KOSHIKAWA

SUMMARY

We have studied the effects of midazolam and flunitrazepam on extracellular concentrations of dopamine, 3,4-dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA) in rat striatum in freely moving animals using in vivo *microdialysis. I.v. injections of midazolam 0.075 and 0.15 mg kg^{-1} decreased striatal dopamine concentrations in a dose-dependent manner without affecting the concentrations of DOPAC and HVA. Flunitrazepam 0.015 and 0.03 mg kg^{-1} also decreased striatal dopamine concentrations in a dose-related manner, but the reductions in DOPAC and HVA were not significant. Flumazenil 6 µg kg^{-1} alone did not affect striatal concentrations of dopamine, DOPAC and HVA, but it prevented the effects of midazolam and flunitrazepam. Flunitrazepam 10 µmol litre^{-1} also decreased striatal dopamine release when infused through a dialysis probe placed into the striatum, but it failed to affect striatal dopamine release when infused into the ipsilateral substantia nigra. Central administrations of midazolam were effective only when the drug was infused into both sites simultaneously (10 and 100 µmol litre^{-1}) or given by intraventricular injection (0.5 and 1 µg). These results suggest that midazolam and flunitrazepam affect striatal dopamine release in a different manner.* (Br. J. Anaesth. 1993; **70**: 181–185)

KEY WORDS

Brain: striatal catecholamines. Hypnotics, benzodiazepines: flunitrazepam, midazolam. Sympathetic nervous system: dopamine.

Behavioural and biochemical studies suggest that there is a functional interaction between γ-aminobutyric acid (GABA)-ergic and dopaminergic neuronal systems, especially at dopaminergic nerve terminals [1–5]. For example, GABA receptor agonists injected into the substantia nigra have been reported to reduce striatal dopamine release [6, 7]. With the brain microdialysis technique, which permits measurement of dopamine and its metabolites in discrete brain regions *in vivo*, it has also been shown that dopamine release in the striatum and nucleus accumbens is decreased by benzodiazepines administered systemically or by local intracerebral injection [8–10]. The actions of the benzodiazepines are caused by enhancement of the action of GABA and are mediated by specific binding sites which are part of the multimolecular GABA$_A$–receptor complex [10–13].

Benzodiazepines are given i.v. to produce either sedation or, when combined with an opioid analgesic, anaesthesia. Midazolam is the drug of choice for these purposes because it does not produce local venous irritation and thrombosis. However, there is still no clear understanding of its mode of action in the central nervous system.

The present study describes the effects of midazolam and of flunitrazepam, in doses similar to those used clinically, on nigrostriatal dopaminergic neuronal activity by using *in vivo* brain microdialysis to measure striatal dopamine release. As the striatum is known to be a terminal area of the dopaminergic neurones that arise from the substantia nigra [14], the compounds were also applied focally to the substantia nigra and the striatum to determine if there were differences between the sites of action of the two drugs.

MATERIALS AND METHODS

Male Sprague–Dawley rats (250–300 g body weight) were studied. Between experiments they were housed in a temperature-controlled environment on a 12-h light–dark cycle (light period 07:00–19:00) with free access to food and water.

Surgery

The rats were anaesthetized with pentobarbitone 50 mg kg^{-1} i.p. The left external jugular vein was cannulated and connected to an osmotic minipump which was filled with heparin–saline 1000 u ml^{-1} and implanted s.c. between the scapulae. The anaesthetized animals were placed in a stereotactic apparatus and unilateral guide cannulae were implanted just above the striatum (antero–posterior (AP) 9.2 mm, medio–lateral (ML) 3.0 mm, dorso–ventral (DV) 7.0 mm) and substantia nigra (AP 3.7 mm, ML 2.0 mm, DV 4.0 mm) according to

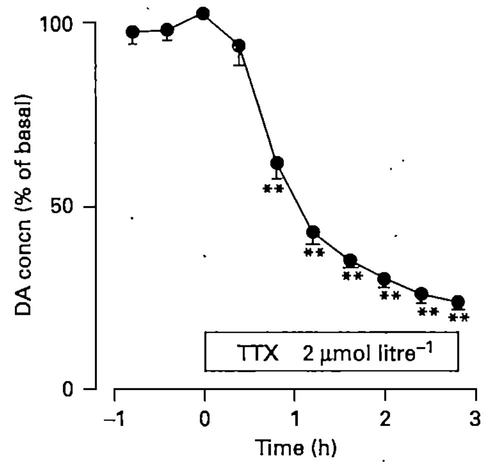

FIG. 2. Effects of infusion of tetrodotoxin (TTX) 2 μmol litre^{-1} on the concentrations of dopamine (DA) in striatal dialysates (mean, SEM of data from six rats). $^{**}P < 0.01$ compared with value just before TTX infusion (paired t test).

the atlas of Paxinos and Watson [15] (fig. 1). The guide cannulae were kept patent between experiments by stainless steel inserts. Before an experiment, the insert was removed and a dialysis probe (3 mm length for the striatum and 2 mm for the substantia nigra, 0.25 mm o.d., 50000 mol. wt "cut-off") was inserted into the guide cannulae so that only the dialysis tubing protruded from the tip. In some animals, a unilateral cannula (0.6 mm o.d., i.d. 0.3 mm) was implanted into the contralateral lateral ventricle (AP 8.2 mm, ML 1.5 mm, DV 7.0 mm) for intraventricular drug injections. The rats were then allowed to recover for a minimum of 7 days before experiments were carried out.

Dialysis and neurochemical measurements

On the day of the experiment, the probes were inserted carefully into the conscious rat and fixed to the guide cannulae by either a screw or dental cement. The rat was then placed in a plexiglass box (30 × 30 cm) and the inlet and outlet tubes connected to a swivel located on a counterbalanced beam to minimize discomfort to the rat. The probes were perfused at a rate of 2.0 μl min^{-1} with Ringer solution (composition (mmol litre^{-1}); NaCl 147, KCl 4, $CaCl_2$ 1.2, $MgCl_2$ 1.1; pH 6.0) and the outflow was connected by Teflon tubing to an HPLC system (EICOM, Kyoto, Japan). Perfusate samples were taken every 25 min for measurement of dopamine, DOPAC and HVA. When the baseline concentration of dopamine had stabilized (at least 4 h after probe insertion), drugs were injected via a jugular cannula. Baseline values were the mean of the last three samples before the injection of drug or infusion of tetrodotoxin. The probes had an *in vitro* recovery of 10–12 % for dopamine, DOPAC and HVA, but the reported concentrations were not adjusted for recovery because this cannot be estimated accurately [16, 17].

Dopamine, DOPAC and HVA were separated on an Eicompak MA-5ODS column (5 μm, 4.6 × 250 mm, Eicom) using citrate buffer 0.07 mol litre^{-1} with octane-sulphonic acid 1.5 mmol litre^{-1}, EDTA 30 μmol litre^{-1}, 15 % methanol (pH 3.9) as the mobile phase at a flow rate of 1.0 ml min^{-1}. The compounds were measured by electrochemical detection using a glassy carbon working electrode set at +700 mV against a silver–silver chloride reference electrode. The detection limit for each of the compounds was about 1 pg per sample. In some experiments, dopamine was separated on an Eicompak CA-5ODS column (5 μm, 4.6 × 250 mm, Eicom) using phosphate buffer 0.1 mol litre^{-1} with octane-sulphonic acid 5.8 mmol litre^{-1}, EDTA 0.3 mmol litre^{-1}, 20 % methanol (pH 6.0) as a mobile phase (flow rate 1.0 ml min^{-1}). The working electrode was set at +400 mV against a silver–silver chloride reference electrode and this gave a detection limit for dopamine of about 500 fg per sample.

Drugs

Drugs used were midazolam (Dormicum, Yamanouchi Pharmaceutical Co., Ltd), flunitrazepam (Rohypnol, Nippon Roche), flumazenil (Ro 15-1788, Hoffmann-La Roche), sulpiride (Dogmatyl, Fujisawa Pharmaceutical Co., Ltd) and tetrodotoxin (Sigma). Drugs were diluted in 0.9 % saline solution for i.v. injections, in Ringer solution for intraventricular injections or added to the perfusion medium for 20 min for intracerebral administration.

Histology

At the end of an experiment, the rat was anaesthetized deeply with pentobarbitone and perfused transcardially with 10 % formalin. The brains were removed, sectioned (50 μm) and stained with cresyl violet to facilitate probe location.

Statistical analysis

All values were expressed as a percentage of baseline and analysed using either paired t test or two-way analysis of variance (ANOVA), as appropriate. Statistical significance was assumed at $P < 0.05$.

RESULTS

The basal concentrations of dopamine, DOPAC and HVA in the dialysate were 9.0 (SEM 1.8) pg/20 min ($n = 6$), 622 (124) pg/20 min and 405 (92) pg/20 min, respectively. The concentrations required 4 h to stabilize after probe insertion, but were then unaffected by saline 1 ml i.v. and remained stable for at least a further 4 h (data not shown). Tetrodotoxin

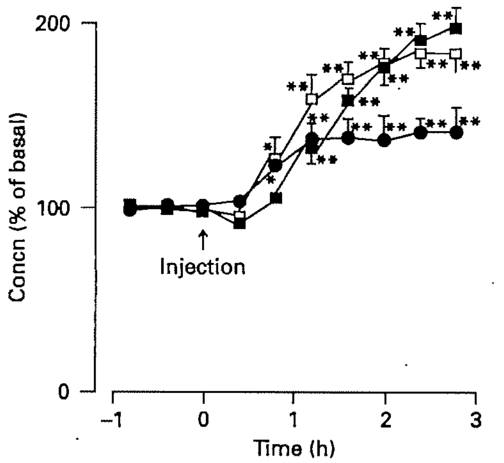

FIG. 3. Effects of i.v. injection of sulpiride 10 mg kg^{-1} on the concentrations of dopamine (●), DOPAC (□) and HVA (■) in striatal dialysates (mean, SEM of data from six rats). $^{*}P < 0.05$; $^{**}P < 0.01$ compared with value just before administration of sulpiride (paired *t* test).

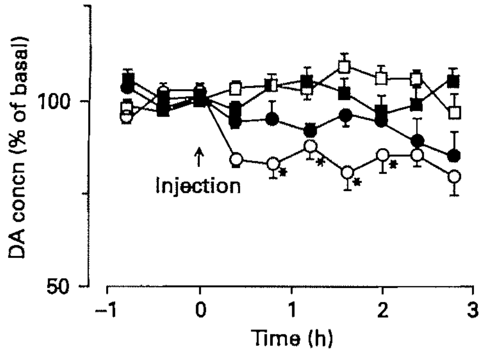

FIG. 4. Effects of midazolam and flumazenil on the concentrations of dopamine (DA) in striatal dialysates (mean, SEM of data from six rats). ● = Midazolam 0.075 mg kg^{-1}; ○ = midazolam 0.15 mg kg^{-1}; □ = flumazenil 6 µg kg^{-1}; ■ = midazolam 0.15 mg kg^{-1} + flumazenil 6 µg kg^{-1}. $^{*}P < 0.05$ compared with value just before administration of drugs (paired *t* test).

2 µmol $litre^{-1}$ infused into the striatum via the dialysis probe reduced basal concentrations of dopamine to approximately 20 % of control (fig. 2).

Sulpiride 10 mg kg^{-1} i.v. increased concentrations of dopamine, DOPAC and HVA in the striatal dialysate. Their values at 3 h after injection were approximately 140 %, 180 % and 200 % of control, respectively (fig. 3).

Midazolam 0.075 mg kg^{-1} and 0.15 mg kg^{-1} i.v. decreased concentrations of dopamine in striatal dialysates in a dose-dependent manner (fig. 4); the overall reductions during a 3-h observation period were 9 % and 17 %, respectively. However, midazolam did not significantly alter the concentrations of DOPAC and HVA (data not shown). The effects of midazolam 0.15 mg kg^{-1} were prevented by co-administration of flumazenil 6 µg kg^{-1}, a benzodiazepine receptor antagonist ($P < 0.01$, two-way ANOVA). Flumazenil alone did not affect concentrations of dopamine, DOPAC and HVA in striatal dialysates. Flunitrazepam 0.15 mg kg^{-1} and 0.03 mg kg^{-1} i.v. also decreased the concentrations of dopamine in striatal dialysates in a dose-related manner (fig. 5); the overall reductions during a 3-h observation period were 8 % (0.015 mg kg^{-1}) and 24 % (0.03 mg kg^{-1}), and tended to decrease concentrations of DOPAC and HVA (data not shown). The peak effects occurred approximately 100 min after injection of flunitrazepam (fig. 5) and were prevented ($P < 0.01$, two-way ANOVA) by co-administration of flumazenil 6 µg kg^{-1}.

A 20-min infusion of flunitrazepam 10 µmol $litre^{-1}$ into the striatum via the dialysis probe significantly reduced (26 % at peak) dialysate concentrations of dopamine for more than 1 h, but similar infusions of midazolam (10 and 100 µmol $litre^{-1}$) were ineffective (fig. 6); midazolam 1 mmol $litre^{-1}$ was also ineffective (data not shown). Neither compound affect striatal dopamine release when infused into the ipsilateral substantia nigra, via a dialysis probe, in a concentration of 100 µmol $litre^{-1}$ (fig. 6). However, midazolam 10 and 100 µmol $litre^{-1}$ infused simultaneously into both sites (striatum and the ipsilateral substantia nigra) or injected into the lateral ventricle (0.5 µg and 1 µg in 5 µl) reduced the concentrations of dopamine in striatal perfusates in a dose-dependent manner (fig.7). The peak reductions in dopamine concentration after simultaneous infusion of midazolam into both the striatum and substantia nigra were 14 % (10 µmol $litre^{-1}$) and 27 % (100 µmol $litre^{-1}$); and peak reductions after injection of midazolam into the lateral ventricle were 14 % (0.5 µg) and 22 % (1 µg).

DISCUSSION

The sodium channel blocker, tetrodotoxin has been used extensively in brain microdialysis experiments to demonstrate that the neurotransmitter and its metabolites detected in the perfusates have been released by action potential-induced depolarization and not released passively as a result of local tissue damage [18]. In the present study, approximately 80 % of the dopamine release was prevented by tetrodotoxin, indicating that it was caused mainly by neural activity.

I.v. midazolam and flunitrazepam decreased striatal dopamine release in a dose-dependent manner, in agreement with an earlier diazepam study [8]. Flunitrazepam was more effective than midazolam in doses similar to those used clinically to produce i.v. sedation and anaesthesia [19–21]. Concentrations of metabolites (DOPAC and HVA) in striatal dialysates tended to decrease after flunitrazepam, but were not affected by i.v. administration of midazolam. This lack of effect on the metabolites can be explained by the fact that the basal extracellular concentrations of DOPAC and HVA were 70 and 45 times greater than the concentration of dopamine; thus it can be assumed that a small (about 20 %) reduction in dopamine release induced by midazolam and flunitrazepam might not be sufficient to change the concentrations of the metabolites. The lack of effect, however, could not be caused by the methodological difficulties in measuring the metabolites as sulpiride, a drug reported to increase the extracellular concentration of dopamine, DOPAC and HVA by block of dopaminergic D_2 autoreceptors, increased the concentrations of these compounds to values similar

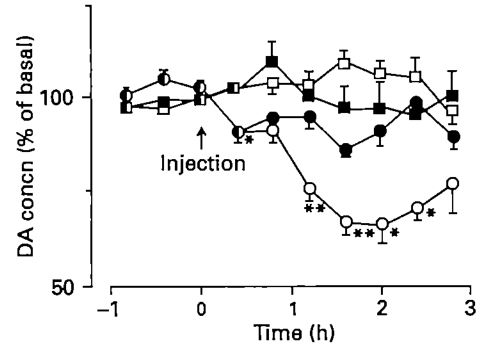

FIG. 5. Effects of flunitrazepam and flumazenil on the concentrations of dopamine (DA) in striatal dialysates (mean, SEM of data from six rats). ● = Flunitrazepam 0.015 mg kg^{-1}; ○ = flunitrazepam 0.03 mg kg^{-1}; □ = flumazenil 6 μg kg^{-1}; ■ = flunitrazepam 0.03 mg kg^{-1} + flumazenil 6 μg kg^{-1}. $*P < 0.05$, $**P < 0.01$ compared with value just before administration of drugs (paired t test).

to those reported previously [22]. The findings of the present study with midazolam and flunitrazepam suggest that, in the dose range used clinically, flunitrazepam had more pronounced effects on dopaminergic pathways than midazolam. These effects of midazolam and flunitrazepam were mediated by the $GABA_A$–benzodiazepine receptor complex, which inhibits the dopaminergic neuronal activity, because they were abolished by flumazenil.

As the striatum is known to be a terminal area of the dopaminergic neurones that arise from the substantia nigra, and their activities are controlled by the GABAergic inhibitory neurones, we were interested in examining the brain site responsible for the ability of the benzodiazepines to reduce the striatal dopamine release. To determine if systemically administered midazolam and flunitrazepam reduced striatal dopamine release by action in the terminal field (striatum) or in the cell body region (substantia nigra) of the nigrostriatal dopaminergic neurones, the compounds were applied directly to these structures by infusion through dialysis probes. Small concentrations of flunitrazepam infused into the striatum were effective, whereas larger concentrations infused into the substantia nigra were ineffective. This suggests that flunitrazepam reduced dopamine release by action at $GABA_A$–benzodiazepine receptors in the terminal field of the dopaminergic pathways. For midazolam to reduce striatal dopamine release, it was necessary to stimulate $GABA_A$–benzodiazepine receptors in both the terminal and cell body regions of the dopaminergic neurones by infusing it into both the striatum and substantia nigra simultaneously or by giving it intraventricularly. The effects of midazolam and flunitrazepam were antagonized by flumazenil, but this does not exclude the possibility that the two compounds were acting on different receptor subtypes [23], because flumazenil is not selective. Regional differences in the effects of benzodiazepines on dopamine release have been shown previously

with systemic and central injections of diazepam and flurazepam which reduced dopamine release in the nucleus accumbens more than in the striatum [8, 10]. These regional differences can be explained by assuming a reduced basal GABA tone or more efficient receptor coupling in the nucleus accumbens and, therefore, more scope for a benzodiazepine effect in the structure. These two possibilities (regional differences in GABA tone and receptor coupling) may also explain the regional differences between the effects of midazolam and flunitrazepam observed in the present study.

ACKNOWLEDGEMENTS

This work was supported by a Grant for Scientific Research from the Ministry of Education, Science and Culture (Japan). Gifts of compounds from Hoffmann-La Roche and Yamanouchi are greatly appreciated.

MATHEMATICAL ANALYSIS OF THE UPPER RESPIRATORY TRACT FROM AN ANTHROPOMETRIC STUDY

G. JANVIER, L. BORDENAVE, P. REVEL, W. ELLISON, A. M. CROS AND S. WINNOCK

SUMMARY

In order to design a new, preformed tracheal tube adapted to the shape of the upper respiratory tract, we have undertaken an anthropometric study from lateral x-rays of the neck in 130 patients with the head in a fixed position. In order to assess different clinical situations, we studied three groups of patients: group 1 = sitting, no tracheal tube; group 2 = supine, no tracheal tube; group 3 = supine, trachea intubated. We defined a standard co-ordinate system and determined mathematical curves for segments of the upper respiratory tract by a polynomial regression method. With these data it was possible to study the effects of physiological variations on the shape of the curves. It was then possible to determine at which region changes occur and the factors influencing these changes. We found that the relative position of the larynx was constant, whereas the hypopharynx exhibited the greatest change with the position of the head. These observations should allow us to construct a new, preformed tracheal tube with elastic compliance properties to fit the changes occurring in the region of the hypopharynx. (Br. J. Anaesth. 1993; **70**: 186–191)

KEY WORDS

Airway: anatomy. Anatomy: mathematical analysis.

Prolonged nasal intubation is complicated by laryngeal lesions in a small number of patients [1]. These are produced by mechanical contact and abrasion at the level of the posterior laryngeal commissure [2, 3]. The semilunar shape of tracheal tubes exerts pressure almost exclusively on the posterior laryngeal area and forces the structure backwards. Movement of the larynx during swallowing causes friction in this area. Modification of the angle at which the tracheal tube enters the larynx may limit contact with the posterior larynx.

The first breakthrough was the introduction of polyvinylchloride tubes with thermal deformation properties. This material has improved laryngeal tolerance of tracheal tubes. However, the rate of deformation of the tube is gradual, and contact pressures are still sufficient to cause ulcers.

A second, more sophisticated, approach was the design of a preformed tube by the Swedish School of Uppsala. This tube was designed with a distal part fitting the laryngotracheal airway. In order to limit the pressure of the tube on the posterior commissure of the larynx, the shape was designed using standard anatomical features of the upper airway. Unfortunately, these tubes produced other problems (positioning problems, pharyngeal intolerance). Indeed, apart from the designers and promoters, few anaesthetists have used this tube.

It is possible that this failure may be explained by poor material conformation to the upper airway and failure of a model based on standard anatomical features.

We have undertaken a mathematical analysis of the pharyngolaryngeal anatomy of the airway based on radiological data and determined the most variable area of the upper airway as a function of factors such as cervicocephalic angulation, height, gender and age.

The goal of this work is to design a new tube in a material which adapts to upper airway morphology, in order to limit further the frequency of post-intubation laryngeal lesions.

PATIENTS AND METHODS

The study was approved by the Ethics Committee of Bordeaux University of Medicine, in accordance with the Helsinki Declaration. The patients studied were taken from three different departments: general surgery, traumatology and otorhinolaryngology.

Lateral cervicocephalic x-rays were taken with the same enlargement and corrected to actual size. For each examination, the patient's head was maintained in a fixed predetermined position by a frame which enabled us to adjust the plane of view with respect to a vertical line. The plane of view was either horizontal or vertical, depending on the patient group.

We studied three groups of adult patients:

Group 1 (sitting) consisted of 30 conscious patients (department of otorhinolaryngology) in the sitting position. In this group, the plane was horizontal.

Group 2 (supine position, non-intubated trachea) consisted of 70 conscious patients (department of traumatology) in the supine position. All the patients had bone fractures of the lower part of the body; patients with trauma to the upper body were excluded. In this group, the plane was vertical (perpendicular to the table).

Group 3 (supine position, trachea intubated and lungs ventilated) consisted of 30 anaesthetized patients (department of general surgery) with a nasotracheal tube. In this group the plane was vertical (perpendicular to the table).

All tracheal intubations were with Portex Blue Line tracheal tubes.

For each x-ray the same orthogonal co-ordinate system was used to trace the shape of the pharyngolaryngeal airway. The co-ordinate axes were defined as follows: the Y axis was the prolongation of the line passing through the upper plane of the vertebral body of the 6th cervical vertebra (C6); the X axis was the line perpendicular to the Y axis and passing through the lower posterior part of the subglottic radio translucency at the C6 level (fig. 1).

Each x-ray was defined with respect to these axes. The points which define the curve of the upper airway were chosen on the posterior wall of the airway. The curve representing the shape of the pharyngolaryngeal airway was obtained by measuring the airway co-ordinates at 1-cm intervals along the X axis, starting at the upper face of C6 and continuing to the bony palate. The upper face of C6 was chosen to define the Y axis because it is situated just below the vertebral body of C5 which, in the adult, is at the same level as the glottis. Moreover, in the median plane, the region C6–7 is in a zone which is inflexible. Thus the co-ordinate axes are not modified by possible extreme lordosis or "straight neck".

The zones studied (fig. 1) were:

Zone L. The region between the upper face of C6 and the projection of the large horn of the hyoid bone on the airway. This region corresponds to the larynx.

Zone H. The region between the hyoid bone and the bony plane of the palate. This region corresponds to the hypopharynx.

Zone V. The region between C6 and the palate, which corresponds to the upper airway.

The set of curves for the same zone varied considerably. This is a reflection of the individual morphological variations in each of the three groups. Consequently, and in accordance with data in the literature [4–7], certain factors were taken into account. These were:

The cervicocephalic angle (the angle between Y axis and the straight line passing by the orbital floor and the external occipital protuberance). This is a good index of individual anatomical variations in cervical rotation. In each of the three groups, the cervicocephalic angle covered a wide range of values and it was necessary to divide the angles into three or four homogenous subgroups (table I).

The subject's height. The patients were classified into two subgroups according to body height: subgroup T1 = patients of height less than 1.65 m (mean 1.6 (SD 0.03) m); subgroup T2 = those of height greater than 1.65 m (mean 1.72 (0.03) m). The mean height of all patients was 1.66 (0.06) m.

The subject's gender.

The subject's age. Patients were classified into two subgroups: subgroup A1 = patients younger than 50 yr (mean 32 yr, range 18–60 yr; subgroup A2 = patients older than 50 yr (mean 68 yr, range 61–87). The mean age for all patients was 53 yr.

X-rays were analysed as follows. First we describe the shape of each of the upper airway curves by a polynomial regression technique. The entire upper airway zone V is well approximated by a cubic polynomial and when the analysis is restricted to either zone L or H, the "best" cubic polynomial has the coefficient of X^3 equal to zero—that is, it is a quadratic polynomial. In all cases, the correlation coefficient for the polynomial regression was > 0.95. This indicates that all the experimental curves were well approximated by the polynomials. Thus we can say that the shape of an upper airway curve in the zones V, L and H can be described adequately by a polynomial of maximum degree of 3.

The second step was to compare the curves for each of the three groups of subjects and the four variation factors in the three zones L, H and V. We chose to use the area between the curve and the X axis as an indicator. The area was calculated from the polynomial equation defining the curve in the zone L, H or V. If two curves are the same, then the areas are the same; if areas are not the same, the two curves are different; if two areas are the same, one cannot conclude anything about the curves. This relatively crude indicator was sufficient for our purposes according to the following reasoning: in a random group of subjects in identical clinical situations, there are wide differences in the cervicocephalic angle; there is a statistically significant correlation between the cervicocephalic angle and the area under the curve. Large differences in the areas in zone H imply differences in the curves.

Thus one can say that in a clinically homogeneous group of subjects there are large variations in the morphology of the upper airway in the zone H and no "standard" model exists.

RESULTS

Shape of the averaged curves

The average curve of all three groups for zone V is shown in figure 2. When the curves of each group are considered separately, major variations become apparent (fig. 3). The difference in the subject's position (supine or sitting), whilst the head is maintained in an apparently controlled position (i.e. horizontal or vertical, depending on the groups), is responsible for these differences.

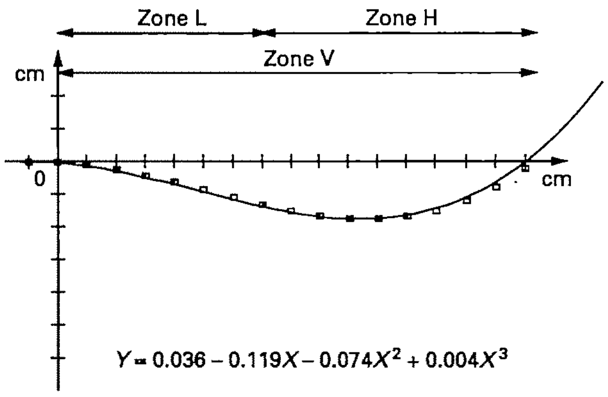

FIG. 2. Airway morphology obtained from all data (curve is the average for all subjects). The three anatomical zones are indicated by arrows.

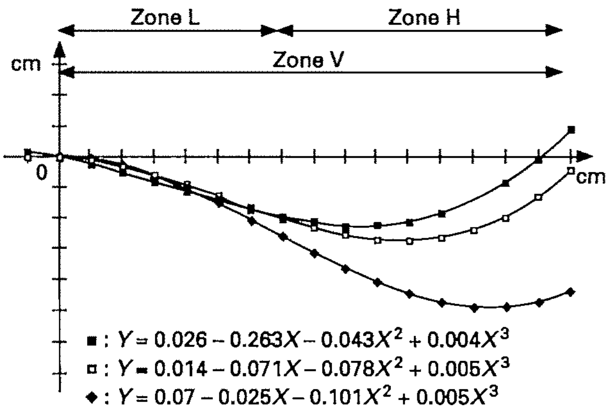

FIG. 3. Representation of the morphology of the upper airway for each of the three groups. Sitting position, no tracheal tube (◆); mean value of the cervicocephalic angle (θ) = 56°. Supine position, no tracheal tube (□); mean value of $\theta = 39°$. Supine position, trachea intubated (■); mean value of $\theta = 38°$.

Variable factors

	Height			Age		
	H1	H2	Mean	A1	A2	Mean
Area (cm²)	17	25	24	15	38	26

pharyngolaryngeal anatomy. The hypopharynx zone is greatly influenced by the values of the cervicocephalic angle.

There was a significant linear correlation between the cervicocephalic angle and the area under the curve. This is illustrated in figure 4 for zone V for group 2 and summarized in table III.

Height. There was no significant correlation between heights of the subjects and the areas under the corresponding curves (table IV). For groups H1 and H2, there was no significant difference between the mean values of the areas.

Gender. There were no statistically significant differences between the area for males and females.

Age. There was a statistically significant correlation between the areas under the curves and the patient's ages (table IV). For the two groups A1 and A2, the difference in the mean areas was significant for zones H and V and non-significant for zone L.

The relative importance of each of the factors on the morphology of the three regions is summarized in table III. In terms of the correlation coefficient, *r*, the cervicocephalic angle is of primary importance. It is in the hypopharynx that the significance is largest; in the larynx, L, the significance is weaker. A relatively good correlation exists between age and morphology of the hypopharynx. However, in this study, we found no significant correlation between height or gender and morphological variations.

DISCUSSION

The object of the study was to demonstrate the existence of variations in a mathematical representation of the pharyngolaryngeal airway in subjects with different body positions, but with the head always positioned in the same way, perpendicular and midline with respect to the frontal body plane. This representation allowed us to identify zones where there were morphological variations as a function of individual anthropometric characteristics.

A possible criticism of this study is that we analysed radiographs in only one plane (profile). Thus it was not possible to obtain a three-dimensional representation for the intubated group. It is well known that a tracheal tube is never in a perfectly median position at the level of the larynx.

Other techniques could have overcome this difficulty, for example computed tomography. Our choice of technique was dictated by economic considerations and by the technical inability to maintain the tubes in reproducible positions. This study has described the shape of the upper respiratory tract in one fixed position of the head; in this respect, it can be considered as a preliminary study which requires further investigations, with different fixed cervicocephalic angles and, ultimately, a dynamic analysis.

A second criticism is the choice of the co-ordinate axes. The Y axis is not situated on any laryngeal structure. It would have been preferable to fix the origin of the axes at some point of the upper respiratory tract. However, taking into account the low mobility of the larynx with respect to the spinal column, our origin is valid [4]. Moreover, our origin is defined in terms of bony structures of the spinal column which are more easily identified on radiographs, than the upper airway.

A third criticism is our choice of using the areas under curve segments to compare the shapes of the segments. If the areas are different, then the curves are different. The converse, of course, is not necessarily true. As the areas in some zones were significantly different, it follows that the shapes of the curves were significantly different, which is sufficient for our purposes.

In spite of these criticisms, the study enabled us to answer some important questions. First, it is not possible to define a unique, "standard" model of the upper laryngeal airway. We have shown that the airway consists of two very different regions: one has a morphology which varies little (larynx), the other has a morphology with random variations (hypopharynx). The principal cause of modification in zone H is the structural change in the head as a function of body position. This influence has already been reported by Alexopoulos and his colleagues in their work on a new intubation device [8–13]. The changes in cervicocephalic angle imply significant deformations in the pharyngolaryngeal structures. There is great mobility in the vertebral segments of the spinal column in zone H; the anatomical representation of the larynx (zone L) is more constant. The small amplitude of movement and the rigidity of the thyroid cartilage are probably responsible for the small amount of variation in position of the larynx in the median plane. Obviously, our study cannot take into account the superoinferior movements of the larynx, because the radiographic analysis was static.

The anatomical variations are essentially interindividual. They are caused by changes in body position without the head being either in flexion or in hyperextension. This accentuates the opening or closing of the cervicocephalic angle and thus it is difficult to predict the position of the cervical spine and the upper airways as a function of head position.

The anatomical variations induced by the cervicocephalic angle are of prime importance in the change in position of the airway. Analysis of age showed that young adults have a more pronounced pharyngeal convexity than older subjects. This may be explained by greater suppleness of the tissues which surround the cephalic extremity. The other variables which we studied (gender, height) were less important in our population.

Any new type of intubation device which has minimum contact pressure in the larynx should be constructed of a material which deforms in the median plane and adapts to the anatomical variations observed in this study. This is particularly true for the hypopharyngeal region.

COMPARISON OF RECOVERY FROM ANAESTHESIA INDUCED IN CHILDREN WITH EITHER PROPOFOL OR THIOPENTONE

C. J. RUNCIE, S. J. MACKENZIE, D. S. ARTHUR AND N. S. MORTON

SUMMARY

We studied 102 children undergoing day-case surgery, allocated randomly to receive either thiopentone 5 mg kg^{-1} or propofol 3 mg kg^{-1} i.v. at induction of anaesthesia. They then inhaled nitrous oxide and halothane in oxygen until a larnygeal mask airway could be inserted. Thereafter, halothane was substituted by isoflurane and analgesia provided by regional nerve block. Recovery from anaesthesia was assessed by the time taken to reach clinically-defined criteria and by calculation of sedation, pain and vomiting scores. In children aged less than 5 yr, only the time to spontaneous eye opening was shorter after propofol induction ($P < 0.05$*). In children aged 5–11 yr, times of spontaneous eye opening, giving name and discharge were shorter after propofol induction (*$P < 0.05$*). These results indicate that propofol hastened early recovery in children undergoing day-case surgery, but earlier discharge occurred only in older children.* (Br. J. Anaesth. 1993; **70**: 192–195)

KEY WORDS

Anaesthesia: paediatric. Anaesthetics, Intravenous: propofol, thiopentone. Recovery.

Propofol has been used since 1984 in adult anaesthesia and has been shown to produce more rapid recovery than thiopentone. It has therefore become popular for day-case anaesthesia. Formal studies of recovery in adults have shown earlier return of clinical criteria of recovery, protective reflexes and psychomotor function after propofol induction [1]. If anaesthesia is maintained with halothane for more than 30 min, however, indices of recovery are similar whichever induction agent is used [2].

In children, early recovery is also more rapid after induction of anaesthesia with propofol than after thiopentone [3]. Recent studies have compared propofol for both induction and maintenance of anaesthesia with thiopentone induction and maintenance by volatile agent [4, 5]. Thus it is not known if induction of anaesthesia with propofol followed by inhalation maintenance in children enhances all aspects of recovery, allowing earlier discharge after day-case surgery. The aim of this study was to compare recovery after propofol and thiopentone induction in children having short general surgical procedures as day-cases with anaesthesia maintained by isoflurane and analgesia provided by local anaesthetic nerve block.

PATIENTS AND METHODS

The study was undertaken in the day-case unit of a regional paediatric hospital. We studied 102 patients, ASA grades I or II, anaesthetized for short general surgical procedures by two of the authors (D.S.A. and C.J.R. or D.S.A. and S.J.M.) after approval from the Hospital Ethics Committee and written informed parental consent. Children having procedures completed in the anaesthetic room (examination under anaesthesia or release of tongue-tie) were excluded. Patients were studied in two age groups: less than 5 yr and 5–11 yr inclusive.

Premedication comprised EMLA emulsion cream (lignocaine 25 mg g^{-1} and prilocaine 25 mg g^{-1}) applied to the dorsa of both hands at least 1 h before induction. Within each age group, patients were allocated randomly (by computer-generated random numbers) to receive either thiopentone 5 mg kg^{-1} or propofol 3 mg kg^{-1} i.v. Increments were given as required to allow the child to tolerate the face mask. Lignocaine 0.3 mg kg^{-1} was added to the propofol to reduce injection pain. All children then inhaled 67% nitrous oxide and an increasing concentration of halothane in oxygen via a Rees T-piece or Bain attachment. A laryngeal mask airway was inserted and an appropriate regional nerve block performed.

After transfer to theatre, all patients received 66% nitrous oxide and 1–1.5% isoflurane in oxygen for maintenance of anaesthesia. Isoflurane was discontinued as the dressings were applied and the laryngeal mask removed; patients were then given 100% oxygen and transferred to the recovery area in the lateral position with the operative site uppermost. Children remained in the recovery area until they could open the eyes spontaneously and they then returned to the adjacent recovery ward.

The following times were recorded by the anaesthetists: start of induction; start of surgery; iso-

flurane discontinued. Thereafter, patients were assessed by the recovery staff, unaware of the induction agent used, who recorded the following times: spontaneous eye opening; giving own name when asked; oral fluid intake; first analgesia; discharge. In addition, they assessed sedation, pain and vomiting by simple four-point scores at 0, 5, 15, 30, 60 and 90 min. Sedation was scored as eyes open spontaneously (1), to speech (2), to shake (3) and unrousable (4). Pain was scored as none (0), mild (1), moderate (2) and severe (3) and vomiting as none (0), nausea only (1), one vomit (2) and more than one vomit (3). For each child, an overall sedation score was calculated as the sum of the six scores obtained during the recovery period. Pain and vomiting scores were calculated similarly. Children were discharged when they were awake and alert, tolerating solids and mobilizing and communicating appropriately for their age.

Data were analysed statistically by the Mann–Whitney test (Minitab statistical software, Pennsylvania, U.S.A.). $P < 0.05$ was taken as significant.

RESULTS

For both age-groups, patient characteristics and operative details were comparable for the two induction agents (table I). The sole exception, in the older children, was that patients receiving propofol were significantly younger than patients receiving thiopentone, although their median weights were not significantly different. One patient in each age group suffered transient hypoxaemia ($Sp_{O_2} < 90\%$) during induction as a result of laryngospasm or breath-holding; each induction agent was involved in one incident.

Recovery times are detailed in table II. In the younger age group, early recovery (as indicated by

TABLE III. *Recovery scores (median (interquartile range)) and 95% confidence intervals for the differences between groups. For each child, scores are calculated as the sum of the six scores obtained during recovery in each category. ns = Not significant*

Vomiting score	0 (0–1)	0 (0–0)	0, 1	ns

the time from discontinuation of isoflurane to spontaneous eye opening) was more rapid after propofol. Other indices of recovery did not differ significantly between the two groups. In the older age group, times to spontaneous eye opening, giving name and discharge were shorter after propofol induction. Times to first oral intake and first analgesia did not differ significantly between groups, but there was a trend in favour of propofol.

In the younger children, postoperative pain scores were significantly greater after propofol (table III).

DISCUSSION

More rapid recovery after induction with propofol than after thiopentone has been well documented in adult outpatient anaesthesia, but not in children. This study was prompted by the authors' clinical impression that the benefits of propofol were less obvious in children and concern that its greater cost was therefore difficult to justify. Our aim was thus to compare propofol with the standard agent, thiopentone, as part of an anaesthetic technique in common use in this unit.

Possible weaknesses in our methodology include the sequential use of both halothane and isoflurane, the inclusion of children younger than 3 yr and significantly greater pain scores after operation in the young children after induction of anaesthesia with propofol. The literature on the recovery characteristics of halothane and isoflurane in children is complicated by induction with inhalation in most studies [6, 7]. In adults, however, spontaneous ventilation of halothane for 30 min after i.v. induction [2] abolished the improvement in recovery seen with propofol. We therefore hoped to avoid both this confounding factor and the airway irritability and desaturation during isoflurane induction [8] by administering halothane until surgical anaesthesia was reached and then changing to isoflurane [9].

Children younger than 3 yr were included as it was the authors' initial impression that the younger the child, the smaller were the differences between propofol and thiopentone. The safety of propofol in this age group has been well documented [10], as has this hospital's clinical experience [11–13]. As Puttick and Rosen have shown that recovery times are more sensitive than the Steward scoring system [4], we used only the former in this study.

The importance of the difference in pain scores between the two groups in younger children is unclear. An explanation for this difference may be that inguinal hernia and hydrocele operations were more common in the group receiving propofol. Children undergoing these procedures often require oral analgesia with paracetamol after operation for peritoneal pain, despite successful regional nerve block. The presence of pain is a possible explanation for the more rapid early recovery in younger children after propofol.

In children younger than 5 yr, only the time to spontaneous eye opening was shorter after propofol than after thiopentone induction. A trend in favour of propofol for other recovery times did not reach statistical significance. In children aged 5–11 yr, times of spontaneous eye opening, giving name and discharge were shorter after propofol. These results are in broad agreement with those of other studies. The degree to which our results can be generalized to paediatric outpatient anaesthesia for other procedures or using other techniques is not clear. Nevertheless, they do suggest that selective use of propofol in older children may allow increased throughput in paediatric day-case units, while moderating increases in cost.

ACUTE HAEMODYNAMIC EFFECT OF SODIUM BICARBONATE IN CANINE RESPIRATORY OR METABOLIC ACIDOSIS

T. NISHIKAWA

SUMMARY

This study has examined the acute haemodynamic effects of 7% sodium bicarbonate solution 1 mmol kg^{-1} (1.2 ml kg^{-1}) administered into the right atrium over 5 s in 25 anaesthetized dogs allocated randomly to respiratory (arterial pH (pH$_a$) 7.18, Pa_{CO_2} 10.1 kPa (n = 8)) or metabolic acidosis (pH$_a$ 7.27, base deficit −9.0 mmol litre^{-1} (n = 7)) or metabolic neutrality (pH$_a$ 7.39 (n = 10)). The pH$_a$ and Pa_{CO_2} in the respiratory acidosis group differed from those in the two other groups ($P < 0.01$). One dog with respiratory acidosis developed progressive circulatory depression and cardiac arrest 6 min after injection of sodium bicarbonate. In the remaining seven dogs with respiratory acidosis, administration of sodium bicarbonate 1 mmol kg^{-1} produced transient decreases in mean arterial pressure, right ventricular dP/dt, and pulmonary blood flow, with increased right atrial pressure, followed by a gradual return of these variables to the baseline. The magnitude of reduction in pulmonary blood flow after sodium bicarbonate was greater in dogs with respiratory acidosis ($P < 0.05$) compared with the changes in the two other groups. The haemodynamic depression after bicarbonate was pronounced during respiratory acidosis and this may be attributed to a smaller pH$_a$ in the respiratory acidosis group, further reduction of intracellular pH, or both. It is suggested that when metabolic acidosis is corrected, bicarbonate should be administered with caution in the presence of respiratory acidosis. (Br. J. Anaesth. 1993; **70**: 196–200)

KEY WORDS

Acid–base equilibrium: metabolic acidosis, respiratory acidosis. Complications: hypercapnia. Pharmacology: sodium bicarbonate.

Sodium bicarbonate has been used widely for the treatment of metabolic acidosis during cardiopulmonary resuscitation [1–3], although its use during cardiopulmonary resuscitation has recently been questioned [4–8].

Sodium bicarbonate has been reported to cause reductions in arterial pressure and myocardial contractility, and often myocardial ischaemia after the i.v. injection [9–13]. A greater reduction in myocardial contractility has been reported during respiratory acidosis than during metabolic acidosis [14, 15], suggesting that intracellular carbon dioxide tension is more potent as a myocardial depressant than pH and bicarbonate concentration. Furthermore, several previous reports have indicated significant differences between the partial pressures of carbon dioxide in arterial and venous blood sampled from patients undergoing cardiopulmonary resuscitation or with circulatory failure (reduced and increased partial pressure of carbon dioxide in the arterial and venous blood, respectively) [16–18]. Consequently, it is likely that haemodynamic depression associated with administration of sodium bicarbonate may be exaggerated during respiratory acidosis. However, there has been no reported *in vivo* investigation examining the detrimental haemodynamic effects of sodium bicarbonate in acid–base derangements. Therefore, the acute haemodynamic effects of sodium bicarbonate solution have been examined during administration into the right atrium in anaesthetized dogs with respiratory or metabolic acidosis and without acidosis.

MATERIALS AND METHODS

Investigations were carried out in 25 adult mongrel dogs of both sexes, weighing 8–13 kg. The study was approved by the Institutional Animal Care and Use Committee. Animals were anaesthetized with i.v. thiamylal 15–20 mg kg^{-1} and the trachea was intubated. The lungs were ventilated mechanically with room air and supplementary oxygen via a cuffed tracheal tube, using a volume-cycled animal ventilator (model R-60, Aika Co., Ltd, Tokyo). End-expiratory concentration of carbon dioxide was monitored continuously using a carbon dioxide analyser (CO_2 Monitor IH31, NEC San-ei Instruments Co., Ltd, Tokyo). Anaesthesia was maintained with 0.7–1.0% halothane inspired in oxygen and air. Suxamethonium 20 mg was given i.v. and thereafter 20 mg h^{-1} was administered i.v. to produce neuromuscular block. During all measurements, pulmonary arterial blood temperature was maintained at 36.5–38.5 °C. Arterial blood was analysed for pH$_a$, Pa_{CO_2}, Pa_{O_2} and base deficit by Acid–Base Laboratory (model ABL 300, Radiometer, Copenhagen), and for

An i.v. cannula was placed in a forelimb vein for constant administration of lactated Ringer's solution at a rate of 10 ml kg^{-1} h^{-1}. Lead II of an electrocardiogram (model 2236A, NEC San-ei Instruments Co., Ltd, Tokyo) was monitored with subcutaneous electrodes in the legs. Heart rate was measured continuously on a beat-to-beat basis by a cardiotachometer (model 1321, NEC San-ei Instruments Co., Ltd, Tokyo) triggered by lead II of the electrocardiogram. Arterial pressure measurements and samples for blood-gas analysis were obtained from a femoral arterial catheter. A flow-directed, balloon-tipped pulmonary artery catheter (model 93-132-5F, Baxter Edwards Laboratories, Irvine, California) was inserted via the right external jugular vein for continuous monitoring of pulmonary artery pressure. Another catheter was positioned in the right atrium through a femoral vein to permit continuous measurement of right atrial pressure (RAP). Calibrated Statham P23ID transducers (Gould, Cleveland, Ohio) were used for pressure measurements. A 5-French gauge catheter-tipped transducer (model MPC-500, Millar Instruments Inc., Houston, Texas) was inserted through the left jugular vein and positioned in the right ventricle to obtain right ventricular pressure and instantaneous rate of increase in right ventricular pressure (RV dP/dt) using a differential amplifier (model 1323, NEC San-ei Instruments Co., Ltd, Tokyo).

After the pulmonary trunk was dissected free of the surrounding tissues through a left-sided thoracotomy in the fourth interspace, an electromagnetic flow probe of appropriate size (model FR 10–12 mm, Nihon-Kohden Co., Ltd, Tokyo) was placed carefully around the pulmonary trunk for continuous measurement of pulmonary blood flow (PBF). The flow probe was calibrated with 0.9% saline solution *in vitro* before implantation, and PBF was measured continuously with a square-wave electromagnetic blood flowmeter (model MFV-3200, Nihon-Kohden Co., Ltd, Tokyo). After surgical preparation, all dogs were allowed a stabilization period of at least 60 min. All recordings were made on the eight-channel recorder (model RECTI-HORIZ-8K, NEC San-ei Instruments Co., Ltd, Tokyo) throughout the investigation.

The animals were allocated randomly to three groups: dogs without acidosis ($n = 10$), with respiratory acidosis ($n = 8$) and with metabolic acidosis ($n = 7$). After a period of stabilization in 10 dogs without respiratory (Pa_{CO_2} 4.5–5.6 kPa) and metabolic acidosis (base deficit > -4 mmol litre^{-1}) the haemodynamic effects of 0.9% saline solution 1.2 ml kg^{-1} were observed and recorded continuously for 3 min when administered over 5 s into the right atrium. Subsequently, after another stabilization period of at least 15 min, 7% sodium bicarbonate solution 1 mmol kg^{-1} (1.2 ml kg^{-1}) was injected over 5 s into the right atrium, and haemodynamic changes were recorded continuously for 3 min. Ventilator settings were kept constant during these haemodynamic measurements.

Respiratory acidosis of Pa_{CO_2} 9.1–10.9 kPa was induced by decreasing ventilatory volume in eight dogs, whereas co-existing metabolic acidosis was not corrected. After a period of stabilization, the same haemodynamic measurements were made for 3 min using 0.9% saline solution 1.2 ml kg^{-1} or 7% sodium bicarbonate solution 1 mmol kg^{-1} when these solutions were injected over 5 s into the right atrium.

Metabolic acidosis of base deficit less than −6 mmol litre^{-1} was induced in seven dogs by continuous i.v. infusion of hydrochloric acid 0.2 mol litre^{-1} at an approximate rate of 80–120 ml h^{-1}, while Pa_{CO_2} was maintained at 4.5–5.6 kPa. After stabilization for at least 15 min, haemodynamic measurements were made for 3 min when 0.9% saline solution 1.2 ml kg^{-1} or 7% sodium bicarbonate solution 1 mmol kg^{-1} was injected over 5 s into the right atrium.

All values are expressed as mean (SEM). Both mean arterial pressure (MAP) and mean pulmonary artery pressure (MPAP) were calculated as diastolic pressure plus one-third of the pulse pressure. Analysis of changes in haemodynamic variables from baseline (30 s, 1 and 3 min) and comparisons of data among the three groups (baseline values and maximal changes from baseline) were performed using one-way or two-way analysis of variance (ANOVA), respectively, and Student's t test with Bonferroni correction. Results were considered statistically significant at $P < 0.05$.

RESULTS

Arterial pH was smallest and Pa_{CO_2} greatest in the respiratory acidosis group, whereas base deficit was most pronounced in the metabolic acidosis group. Blood sodium concentration was smallest in the metabolic acidosis group, but within the normal range (table I).

Baseline RAP before administration of 0.9% saline solution was significantly greater in respiratory acidosis compared with the two other groups ($P < 0.05$) (table II). Administration of 0.9% saline solution 1.2 ml kg^{-1} into the right atrium over 5 s caused small but significant increases in RAP in all three groups, and significant increases in MPAP and PBF in the metabolic acidosis and non-acidosis groups.

Before administration of sodium bicarbonate, baseline RAP was greater in the respiratory acidosis group compared with the two other groups ($P < 0.05$) (table III). Both acidosis groups had decreased baseline MAP values; in the metabolic acidosis group, the difference just reached significance compared with the non-acidosis group ($P < 0.05$).

The most frequently observed haemodynamic changes after administration of sodium bicarbonate included transient decreases in MAP and RV d*P*/d*t*, and increased RAP, followed by gradual return to baseline values, or greater. No significant changes in HR were observed in all groups. However, PBF responses to a 5-s administration of sodium bi-

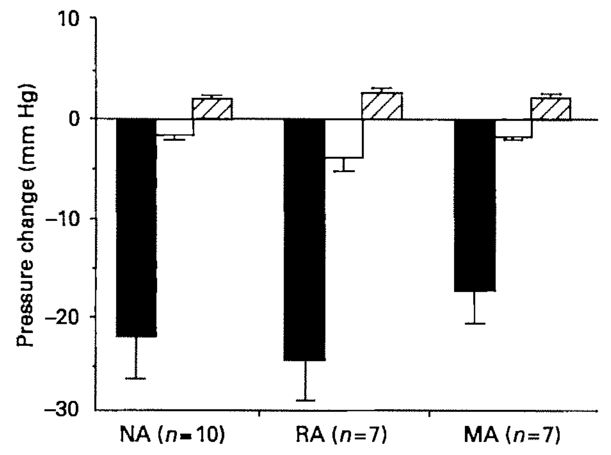

FIG. 1. Maximal changes (mean, SEM) in mean arterial pressure (MAP) (■), mean pulmonary artery pressure (MPAP) (□) and right atrial pressure (RAP) (▨) from baseline values within 1 min after the administration of sodium bicarbonate 1 mmol kg^{-1} into the right atrium in dogs with no acidosis (NA), respiratory acidosis (RA) and metabolic acidosis (MA). The mean (SEM) times at which maximal changes of MAP, MPAP and RAP occurred after the administration of sodium bicarbonate were: MAP—25 (3) s, 34 (5) s, 24 (4) s; MPAP—20 (1) s, 27 (3) s, 17 (3) s; RAP—24 (3) s, 23 (5) s, 21 (3) s in non-acidosis, respiratory acidosis and metabolic acidosis groups, respectively. There were no significant differences in these haemodynamic variables among the three groups.

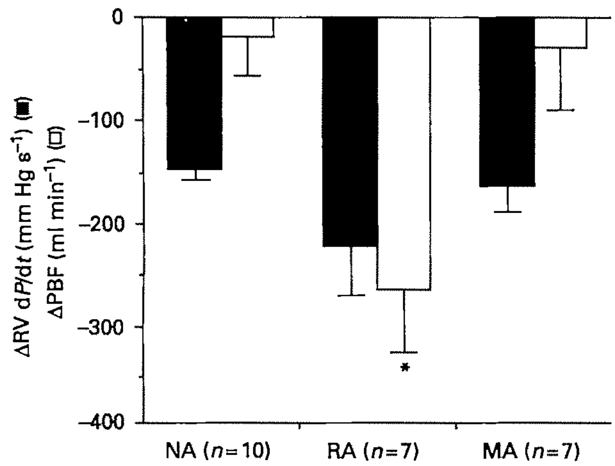

FIG. 2. Maximal changes (mean, SEM) in right ventricular dP/dt (RV dP/dt) (■) and pulmonary blood flow (PBF) (□) from baseline values within 1 min after the administration of sodium bicarbonate 1 mmol kg^{-1} into the right atrium in dogs with no acidosis (NA), respiratory acidosis (RA) and metabolic acidosis (MA). The mean (SEM) times at which maximal changes of RV dP/dt and PBF occurred after the administration of sodium bicarbonate were: RV dP/dt—19 (2) s, 23 (3) s, 21 (1) s; PBF—24 (2) s, 30 (2) s, 24 (2) s in non-acidosis, respiratory acidosis and metabolic acidosis groups, respectively. $^*P < 0.05$ compared with non-acidosis and metabolic acidosis groups.

carbonate were not consistent among the three groups (table III); a profound reduction of PBF occurred immediately after injection of sodium bicarbonate in the respiratory acidosis group.

In one of the eight dogs with respiratory acidosis, progressive circulatory depression and cardiac arrest occurred 6 min after the injection of sodium bicarbonate; the data of this dog were excluded from figures 1 and 2, which show maximal changes in haemodynamic values within 1 min after injection of sodium bicarbonate. Although MAP, MPAP and RAP of the three groups showed comparable alterations from baseline values after administration of sodium bicarbonate (fig. 1), there was a significant reduction in PBF in the respiratory acidosis group compared with those in the two other groups ($P < 0.05$) (fig. 2).

DISCUSSION

This study has shown that the haemodynamic depression after administration of 7% sodium bicarbonate 1 mmol kg^{-1} into the right atrium over a period of 5 s was augmented by respiratory acidosis. As the haemodynamic alterations associated with sodium bicarbonate were smaller in dogs without respiratory acidosis, the considerable haemodynamic deterioration after sodium bicarbonate in dogs with respiratory acidosis could be attributed to a decreased $\mathrm{pH_a}$ before bicarbonate administration, further reduction of intracellular pH caused by diffusion of carbon dioxide into the myocardial cells or both. The results suggest that, if severe respiratory acidosis exists, sodium bicarbonate should be given cautiously to correct metabolic acidosis.

Although there are conflicting data [12–15, 19, 20] on the major determinants of myocardial performance during acid–base disturbances (intra- or extracellular pH, $P\mathrm{CO_2}$ and bicarbonate), $P\mathrm{CO_2}$ or intracellular pH appears to be more important. In an animal study [15] of simultaneous changes in intracellular and extracellular pH during acidosis, at the same extracellular pH, it was shown that respiratory acidosis caused greater depression in myocardial contractility and greater intracellular acidosis of the heart than metabolic acidosis. In addition, intracellular acidosis may be aggravated by administration of sodium bicarbonate ("paradoxical" acidosis) [4, 21], because of free diffusion of carbon dioxide, generated by bicarbonate, into the cells. In the present study, extracellular pH in the respiratory acidosis group was 7.18 (table I) and intracellular pH may have decreased to less than 7.00 [21]. This may account for the observation that haemodynamic depression was most marked (table II, fig. 2) and there was a cardiac arrest in the respiratory acidosis group. However, a further study should be undertaken to evaluate the haemodynamic effect of sodium bicarbonate during respiratory and metabolic acidosis at the same arterial pH, as the $\mathrm{pH_a}$ was significantly greater in the metabolic acidosis group than in the respiratory acidosis group in the present study, and may have contributed in part to the lesser haemodynamic depression after sodium bicarbonate during metabolic acidosis.

The depressant effect of carbon dioxide on myocardial contractility seems to be evident when the $\mathrm{pH_a}$ decreases to less than 7.00 during respiratory acidosis [22–24]. Hypercapnia is accompanied by systemic peripheral vasoconstriction [22]. However, there are also conflicting data showing increased cardiac output associated with systemic vasodilatation during respiratory acidosis [25]. This discrepancy may be attributed to different anaesthetic agents used and the stimulant effect of carbon dioxide on the sympathoadrenal system, which can compensate for the direct cardiovascular depressant effect of carbon dioxide. It is likely, therefore, that the significant increase in RAP observed in the respiratory acidosis group (tables II, III) was caused by peripheral vasoconstriction secondary to hypercapnia.

The dose of sodium bicarbonate used in the present study was based on the standards for cardiopulmonary resuscitation [3] and previous reports [7, 9]. The injection rate of sodium bicarbonate is likely to affect the degree of associated haemodynamic alterations to as great an extent as the total dose. However, there is no "standard" rate of sodium bicarbonate administration in cardiopulmonary resuscitation [3]. The 5-s period of administration of sodium bicarbonate was chosen according to previous experimental reports in which sodium bicarbonate approximately 1 mmol kg^{-1} was given as a bolus injection or over 5–15 s [1, 2, 7, 9].

In conclusion, this experiment suggests that haemodynamic depression after the i.v. administration of sodium bicarbonate is pronounced during respiratory acidosis. If severe respiratory acidosis exists, bicarbonate should be administered cautiously for the correction of metabolic acidosis.

PLASMA CONCENTRATIONS OF BUPIVACAINE AND ITS ENANTIOMERS DURING CONTINUOUS EXTRAPLEURAL INTERCOSTAL NERVE BLOCK

R. G. BERRISFORD, S. SABANATHAN, A. J. MEARNS, B. J. CLARKE AND A. HAMDI

SUMMARY

Plasma concentrations of bupivacaine have been measured in 12 patients given bupivacaine through a paravertebral catheter placed under direct vision at thoracotomy. After an initial bolus of 0.5% bupivacaine 20 ml, mean (SEM) $C_P$max was 1.45 (0.32) $\mu g\ ml^{-1}$ and median (range) t$C_P$max was 25 (10–60) min. A concentration of 4.43 $\mu g\ ml^{-1}$ measured in one patient was not associated with toxic signs. During continuous infusion of bupivacaine for 120 h, $C_P$max was 4.9 (0.7) $\mu g\ ml^{-1}$ and t$C_P$max 48 (5–96) h. No symptoms or signs of toxicity occurred. Separate measurement of R- and S-bupivacaine concentrations demonstrated significantly different concentration–time profiles. (Br. J. Anaesth. 1993; **70**: 201–204)

KEY WORDS

Anaesthetics, local: bupivacaine. Anaesthetic techniques, regional: paravertebral block. Pharmacokinetics: bupivacaine infusions. Toxicity.

Continuous extrapleural intercostal nerve block is an effective method of analgesia for patients undergoing thoracotomy [1]. It has been shown to reduce pain scores, minimize reduction in lung volumes [2] and reduce the incidence of pulmonary complications after lung resection [3]. While the rate at which bupivacaine is infused does not exceed the maximum recommended dose (2 $mg\ kg^{-1}/4\ h$), there remains the potential for bupivacaine toxicity.

Bupivacaine is a synthetic chiral compound comprising two optically active enantiomers, R-bupivacaine and S-bupivacaine. It is administered as a racemic mixture of these two enantiomers (RS-bupivacaine). As enantiomers may differ in their pharmacokinetics, pharmacological effects and toxicity, full evaluation of the potential toxicity of bupivacaine requires separate measurement of R- and S-enantiomers [4–6].

This study was undertaken to measure plasma bupivacaine concentrations achieved during continuous extrapleural intercostal nerve block.

PATIENTS AND METHODS

The study was approved by the local Ethics Committee and all patients gave informed consent. Twelve consecutive patients (ASA I) undergoing thoracotomy for anti-reflux procedures were investigated. Patients were excluded if they received a peroperative blood transfusion, lost more than 1 litre of blood, or were taking histamine antagonists which may affect bupivacaine metabolism [7]. Hepatic and renal disease was excluded on the basis of preoperative blood tests.

All patients received a sleep dose of thiopentone, vecuronium 0.1 $mg\ kg^{-1}$ and phenoperidine (1 mg if weight less than 50 kg, 2 mg if weight greater than 50 kg). Intermittent positive pressure ventilation was used with 66% nitrous oxide in oxygen supplemented with 0–1% isoflurane or 0–1.5% enflurane. Mean end-tidal carbon dioxide concentration was maintained at 4–5% and pulse oximetry saturation greater than 90%.

Towards the end of the operation, a 16-gauge extradural catheter was placed against the paravertebral space after the posterior parietal pleura had been raised as described previously [1, 2]. The tip of the catheter was inserted into the paravertebral space through a defect made in the extrapleural fascia [8].

A bolus of 0.5% plain bupivacaine 20 ml was given through the catheter when it had been secured in place ($t = 0$). The continuous infusion of bupivacaine was started 1 h later ($t = 60$ min). To remain within the guideline dosage of 2 $mg\ kg^{-1}/4\ h$, the rate of infusion was set according to body weight and continued until the morning of the fifth day after operation: 50–59 kg—5 $ml\ h^{-1}$ (25 $\mu g\ h^{-1}$); 60–69 kg—6 $ml\ h^{-1}$ (30 $\mu g\ h^{-1}$); 70–79 kg—7 $ml\ h^{-1}$ (35 $\mu g\ h^{-1}$); 80–89 kg—8 $ml\ h^{-1}$ (40 $\mu g\ h^{-1}$); 90–99 kg—9 $ml\ h^{-1}$ (45 $\mu g\ h^{-1}$); more than 100 kg—10 $ml\ h^{-1}$ (50 $\mu g\ h^{-1}$).

Blood samples were collected from a central venous catheter into pre-cooled polypropylene tubes, centrifuged and stored at −20 °C until required for analysis. Samples were collected at 10, 20, 30, 45 and 60 min after initial bolus injection, 5, 20, 60, 120, 180, 240, 360 and 480 min after the infusion began and at 24, 48, 72, 96 and 120 h after operation.

Median (range)	—	25 (10–60)

Plasma concentrations of bupivacaine were measured by high pressure liquid chromatography (HPLC). Total bupivacaine with its R- and S-enantiomers were measured by a coupled chiral–achiral HPLC method [9].

Maximum plasma concentration of bupivacaine ($C_P$max) and the time it was attained (tC_Pmax) during initial bolus and during continuous infusion were recorded.

Analysis of variance was used to determine the significance of differences between concentrations of RS-, R- and S-bupivacaine.

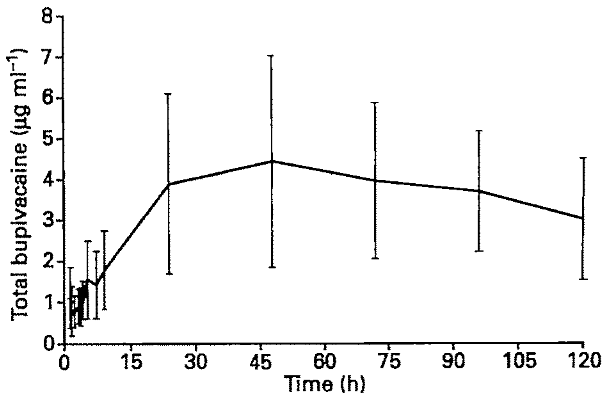

FIG. 3. Mean (SEM) plasma bupivacaine concentrations (racemic) after continuous paravertebral infusion. Time zero represents 60 min after bolus injection.

RESULTS

Patient characteristics were: age range 27–64 yr, mean (SEM) weight 75.2 (3.9) kg, sex ratio 6:6. No patient reported symptoms of bupivacaine toxicity, neither were any signs of toxicity observed.

Bupivacaine assay

For the concentration range 1–20 µg ml^{-1} of aqueous standards, the regression equation was $y = 8.14x + 1.06$ ($r = 0.999$, $n = 12$). Repeatability for a standard at 10 µg ml^{-1} was 0.58 % ($n = 8$). The limit of detection for bupivacaine in pooled serum was 13 ng on column for a 50-µl injection [9].

Bupivacaine concentrations after bolus injection

RS-Bupivacaine concentrations measured during the first 60 min after injection are shown for individual patients in figure 1; mean values are shown in figure 2. Values for $C_P$max are shown in table I. One patient exhibited greater concentrations compared with the remainder, although they were not associated with symptoms or signs of toxicity. Mean (SEM) $C_P$max was 1.45 (0.32) µg ml^{-1} and median tC_Pmax 25 min (range 10–60 min), although there was wide variation between individual patients.

Bupivacaine concentrations during infusion

After the initial peak after the bolus injection, there was a gradual increase to a mean (SEM) peak RS-bupivacaine concentration of 4.92 (0.7) µg ml^{-1} at 48 (5–96) h (fig. 3, table II). Subsequent concentrations were smaller, although this decrease was not significant. The greatest concentration of RS-bupivacaine measured in any patient was 7.48 µg ml^{-1}. However, there were no symptoms or signs of bupivacaine toxicity.

Plasma concentrations of R- and S-bupivacaine are shown in figure 4. Concentrations differed significantly at 30, 45, 210, 300 and 420 min and at 24, 48 and 96 h.

DISCUSSION

There is an extensive literature on plasma bupivacaine concentrations after injection for regional anaesthetic techniques [10]. However, to our knowl-

edge, bupivacaine concentrations attained during bolus and continuous paravertebral infusion have not been documented before.

After bolus paravertebral injection, mean $C_P$max (1.45 μg ml^{-1}) was less than the presumed toxic plasma concentration. Smaller concentrations have been measured when other regional techniques have been used for post-thoracotomy analgesia [11]. Median tC_Pmax (25 min) was similar to tC_Pmax measured after other techniques. For comparison, tC_Pmax after intercostal injection was 10–20 min, after extradural injection 15–30 min [12] and after interpleural injection, 20 min [13].

Systemic accumulation of bupivacaine seen in this study during continuous paravertebral infusion occurs also after continuous infusion via other routes. Increasing concentrations, in some cases greater than 4 μg ml^{-1}, have been measured after 48 h of extradural infusion [14]. After continuous interpleural infusion, mean venous concentrations of bupivacaine 2.29 μg ml^{-1} (range 0.72–4.24 μg ml^{-1}) at 48 h [10] and 4.25 μg ml^{-1} and 2.5 μg ml^{-1} at 24 h [15] have been measured. None of these authors reported associated toxicity. We are not aware of any study which has documented bupivacaine concentrations after 120 h of infusion by any route.

Systemic accumulation may be explained in terms of plasma protein binding. Bupivacaine is 92% bound to plasma proteins in man (at 1.0 μg ml^{-1}) [16] and only free drug concentration determines biological action and therefore toxicity. Thus total drug concentration measured in most studies does not reflect active (potentially toxic) drug concentrations. A marked increase in plasma alpha$_1$ acid glycoprotein occurs after surgery and is associated with increased plasma drug binding [17]. Therefore, although total drug concentration may exceed "minimal toxic concentration", free drug concentration may remain within acceptable limits after operation [18]. This has been confirmed by a study in patients undergoing cholecystectomy given i.v. bupivacaine; total plasma drug concentrations doubled after operation, whilst unbound (active) drug concentrations were similar to those measured before operation [19].

REVIEW ARTICLE

THE HAEMOSTATIC RESPONSE TO SURGERY AND TRAUMA

W. G. MURPHY, M. J. DAVIES AND A. EDUARDO

Perceptions of the physiological mechanisms of coagulation are undergoing substantial changes. For example, the classical divide of coagulation cascades into intrinsic and extrinsic systems is not relevant to humans: no coagulopathy, or indeed disease state, is associated with deficiencies of several of the proteins of the intrinsic system. The cascade of thrombin generation is via tissue factor, factor VII and factors IX and X, with an absolute requirement for platelet phospholipid matrix and factors VIII:C and V as cofactors (fig. 1). Perhaps of greater importance in practical understanding of the complex acquired coagulopathies such as disseminated intravascular coagulation (DIC) or those following cardiopulmonary bypass surgery or massive resuscitation is that seemingly subtle changes, not measured easily by current coagulation tests, may be far more important than the changes measured by those tests. For example, inability of platelets to stick at sites of injury may be a more limiting factor in haemostasis than the concentrations of circulating soluble coagulation factors. The recent demonstration that large doses of the protease inhibitor, aprotinin, almost completely abolish the acquired coagulopathy of cardiopulmonary bypass surgery (and improve haemostasis in other surgical states) has taken the haemostasis world by surprise; the discovery was serendipitous and the mechanism is still speculative. Attention is now focused on the action of proteases on the platelet surface. What is clear is that there has been a fundamental gap in our understanding of the genesis of coagulopathy in cardiopulmonary bypass; this gap persists, and may also be involved in the understanding of other acquired coagulopathies.

THE PHYSIOLOGY OF COAGULATION: AN OVERVIEW

After vessel rupture, several sequential events occur that attempt to plug the hole. Obviously, physiological coagulation cannot stop large volume flow through a severed vessel (although "surgical" bleeding may be overdiagnosed [77]: a poor clot may disintegrate rapidly, allowing what would otherwise have been a securely haemostatic vessel to rebleed).

The starting point is that the soluble protein, von Willebrand factor, must attach to the exposed subendothelium in the damaged vessel. Failure here results in failure to achieve haemostasis. Absence of von Willebrand factor (von Willebrand's disease), or rarely, absence or malfunction of collagen (as may arise in scurvy) in the subendothelium, prevents this first step taking place.

If von Willebrand factor has bound, and if that von Willebrand factor is structurally normal, then the next step can proceed. Some details of this step remain to be clarified, but essentially the subendothelium-bound von Willebrand factor now exposes multiple intrinsic binding sites for a specific platelet membrane structure termed GPIb. This glycoprotein is fully functional on the resting circulating platelet. *It is likely that this von Willebrand factor–GPIb binding is of critical importance in the complex surgical coagulopathies*, and it is possible that manipulation of this event is a prime site of action of aprotinin.

This step fails if:

(a) There are too few platelets. Haemostasis may be impaired when the circulating platelet count de-

creases to less than 100×10^9 litre^{-1}. At a circulating count of less than 50×10^9 litre^{-1}, a critical impairment of haemostatic response to surgery or trauma can be anticipated and spontaneous bleeding may occasionally occur [13].

(b) The platelets are not delivered to the periphery of the flowing blood. Platelets in arterial and arteriolar blood are not distributed evenly across the column of blood, but are concentrated in the peripheral areas, while the red cells preferentially flow in the central area. These flow characteristics are not maintained when the PCV decreases to less than 20%, with a result that there is a functional dilution of platelets within the blood stream [21], which may impair haemostasis.

(c) The platelets lack the GPIb receptor. This condition may arise during cardiopulmonary bypass, from proteolytic degradation of the receptor [65]. It is a feature of platelets for transfusion that have been stored for 3 days or longer [8, 10, 26]. It also arises in the rare congenital Bernard–Soulier syndrome.

(d) The GPIb receptor is already occupied, or is otherwise functionally inert. Failure of initial platelet adhesion may contribute to coagulopathy in myeloma, in some cases of idiopathic thrombocytopenic purpura [18], and after infusion of Dextran [1].

Failure of the GPIb–von Willebrand factor axis results in total haemostatic failure—the next two steps of haemostasis (the generation of a platelet plug and the solidification of that plug by fibrin) are completely dependent on platelets adhering at the site of injury.

The only practicable test of this axis in acute clinical situations is the bleeding time; other tests such as the platelet count and the prothrombin or partial thromboplastin times do not reflect the status of this essential axis. The bleeding time has poor predictive value as a *screening* test in the general population; however, in a patient with a clinically manifest coagulopathy it is a useful indicator of impairment of this part of platelet function [47].

The platelet that adheres at a site of injury is exposed to several activating stimuli and to concentrations of adhesive proteins, that enhance the initial adhesion and that allow other platelets to accrete on those already attached. Activation of platelets by thrombin, ADP and perhaps by von Willebrand factor–GPIb binding itself [44] progresses through several metabolic pathways [45] to induce spreading of the platelets over the damaged surface. Secretion of several procoagulant and ligand proteins from the alpha and dense granules of the platelet occurs, together with exposure of other binding sites on the platelet surface, important among which are glycoprotein IIbIIIa, which binds von Willebrand factor and fibrinogen under physiological conditions [34, 75], and the phospholipid, phosphatidylserine, which serves as the essential surface upon which the next step takes place.

Platelets will not form a satisfactory platelet plug or a base for subsequent fibrin formation if they are too few, or functionally inept. Prior activation, such as may occur in cardiopulmonary bypass, *ex vivo* storage, or exposure to aspirin or similar drugs, uraemia and acute and chronic alcohol ingestion, may result in acquired functional compromise [19, 28, 74]. Congenitally impaired platelet function is not rare.

The next step involves the laying down of a strong fibrin mesh through the platelet plug. A sequence of proenzymes and cofactors, present in trace amounts in plasma, are concentrated on the surface of activated platelets and activated by their predecessors, and often successors, in the "cascade" (an established, if inappropriate, name: explosion is a better term) to generate the final enzyme, thrombin. Thrombin then directly cleaves the molecule fibrinogen, present in vast amounts in plasma, to produce the spontaneous, self-linking species, fibrin.

Absence or dysfunction of the factors involved in this sequence results in a coagulopathy. Congenital deficiencies are notable for being uncommon and reasonably well characterized. Predictable and well characterized acquired deficiencies or dysfunctions of the soluble clotting factors arise with anticoagulant therapy, vitamin K deficiency and liver disease. Deficiency and dysfunction of this step of coagulation form part of the complex acquired coagulopathies: disseminated intravascular coagulation (DIC), massive resuscitation, cardiopulmonary bypass and liver transplantation.

At the same time as the procoagulant mechanisms are initiated, several anticoagulant mechanisms begin, that serve to limit the extent of clotting. These anticoagulant mechanisms are the fibrinolytic system, the antithrombin pathways (one involving antithrombin III and another involving proteins C and S) and the extrinsic pathway inhibitor pathway, which inhibits the factor VIIa–thromboplastin complex. Of these mechanisms, fibrinolysis contributes to bleeding problems in surgical patients.

In the same way that clotting of fibrinogen has thrombin as its main effector, fibrinolysis has plasmin as its main enzyme. Plasmin is generated by enzymatic cleavage of the circulating inactive form, plasminogen. Plasminogen may be activated by several enzymes, of which tissue plasminogen activator (tPA) is the most important. tPA is released from endothelial cells in response to several stimuli, including thrombin. By binding to fibrinogen, it is incorporated into the clot, where it can activate fibrinogen-bound plasminogen and where it avoids rapid inactivation by potent circulating inhibitors. Normally, plasmin activity is limited by circulating inhibitors to fibrin or fibrinogen in clots, and perhaps to the platelet surface. Widespread activation of the fibrinolytic system can occur in DIC and can be achieved therapeutically by infusions of streptokinase or tPA.

Plasmin can also hydrolyse several other proteins apart from fibrinogen and fibrin, including factors V and VIII:C and the platelet membrane glycoprotein, GPIb. It is also capable of activating platelets directly [15]. Direct measurement of *in vivo* plasmin activity can be achieved by measuring specific peptides cleaved from fibrinogen by plasmin, including B-beta 1-42, B-beta 15-42, D-dimers (from fibrin crosslinked by thrombin-activated factor XIII) and fibrin(ogen) degradation products (FDP). D-dimers and FDP are the most clinically useful markers, but are affected by hepatic or renal failure. The beta peptides are suitable only for research studies.

COMPLEX ACQUIRED COAGULOPATHIES IN SURGICAL PATIENTS

Complex acquired coagulopathy may arise in many surgical settings associated with infection, severe tissue damage, massive blood loss or prolonged hypotension, or in the specific settings of cardiopulmonary bypass and liver transplantation. The patient may or may not have had a pre-existing coagulopathy associated with liver disease, drug ingestion, other co-existing disease or underlying congenital defect. In addition, more than one of these coagulopathies may arise in the same patient; for example, a degree of disseminated intravascular coagulation often complicates the coagulopathy of massive transfusion.

The complex acquired coagulopathies present difficulties in diagnosis and in management. Standard tests of coagulation are often unhelpful and may be misleading; management strategies tend to be empirical, limited and controversial.

Coagulopathy After Hypovolaemic Shock and Massive Transfusion

Patients who are being or have been resuscitated from severe haemorrhage are at risk of developing a clinically significant coagulopathy that can contribute to the morbidity and mortality of their underlying disorder. As with other bleeding disorders in surgical patients, the diagnosis is based mainly on clinical grounds, with laboratory investigation contributing subsidiary information. Even the development of a potential coagulopathy is currently better assessed by an appreciation of the recent clinical history than by the coagulation screen.

Two separate mechanisms contribute to the coagulopathy: dilution of platelets and soluble clotting factors, and consumption of platelets and factors from activation of tissue factor and tissue plasminogen activator from the ischaemic or traumatized tissues [35, 37].

Diagnosis and management

The presence of an acquired coagulopathy after hypotension and resuscitation or during treatment of massive bleeding without concurrent prolonged hypotension manifests itself clinically by diffuse oozing from the trauma or surgical wounds and by bleeding around the sites of insertion of i.v. catheters [13]. The same principles that underlie general clinical diagnostics should apply: there is usually a relevant history, and there are clinical signs as listed above. Laboratory testing should not be intended to establish the presence of a coagulopathy; this is done clinically. Instead, it should be intended to shed light on contributory or underlying mechanisms and to guide the extent, but not the nature, of therapy required.

Case history

All complex acquired coagulopathies may be worsened by pre-existing coagulopathy, such as von Willebrand's disease, thrombocytopenia or previous ingestion of aspirin or other non-steroidal anti-inflammatory drugs. However, the most relevant information is the immediate history—duration of hypotension and extent of resuscitation. Where approximately one blood volume has been replaced by infusion, a clinical coagulopathy may arise by dilutional thrombocytopenia, irrespective of any contributory effect of hypotension; by the time about two blood volumes have been replaced, a critical dilution of soluble clotting factors has been approached [17].

Laboratory investigation

Platelet count, PCV, prothrombin times (PT) and fibrinogen concentrations are important measurements to assess the extent of coagulopathy but not, as stressed above, the existence of one. In addition, these tests are poor predictions of the likelihood of onset of abnormal bleeding [13, 17]. Partial thromboplastin time (PTT) and D-dimers may be used as additional tests [13].

Coagulopathy from dilutional thrombocytopenia is usually associated with a circulating platelet count of 100×10^9 litre^{-1} or less [17]. Whether or not the measured platelets are functional is not demonstrable by routine laboratory investigations. The circulating platelets may not be functional, either because they have been activated enzymatically or degraded, or because non-functional platelets from stored blood are being counted.

Prolongation of the PT or PTT after massive transfusion in the absence of DIC is caused primarily by hypofibrinogenaemia; the presence of a consumptive coagulopathy leads to loss of other soluble factors, particularly factors V and VIII:C.

Management of coagulopathy arising during resuscitation in massive transfusion

It follows from the studies of the mechanisms of coagulopathy in these patients that bleeding should be treated, in the first instance, by platelet transfusion without a great deal of regard being paid to the circulating platelet count. In the presence of life-threatening bleeding or after head injury, a sufficient dose of platelets should be provided to attempt to increase the concentration of functional platelets towards 100×10^9 litre^{-1}. It is not possible to judge this accurately, but the required dose is about $6–8 \times 10^{11}$ platelets in an adult—about 10–12 units of platelets. Where haemorrhage is less critical, 50 % of this dose should suffice; the effect should be judged clinically.

If laboratory testing indicates that hypofibrinogenaemia or dilutional or consumptive coagulopathy is present, or when time does not allow waiting for the result, cryoprecipitate and fresh frozen plasma are required in addition to platelets when:

a) The plasma fibrinogen concentration is less than 0.8 g litre^{-1}, when fibrinogen should be replaced with cryoprecipitate: 10 units of cryoprecipitate increases the fibrinogen concentration by about 1 g litre^{-1} in an adult.

b) The PT is greater than 1.8 the normal control and the fibrinogen is greater than 0.8 g litre^{-1}, when fresh frozen plasma should be given to restore deficiencies of other clotting factors, particularly factors V and VIII:C. Two units of fresh frozen plasma (FPP) (approximately 600 ml) is the minimum dose. The effect should be monitored clinically (reversal of coagulopathy) and by laboratory testing.

The use of prophylactic infusions of plasma, or of platelets, have not been found to be justified during massive transfusions in the absence of clinical evidence of coagulopathy [13, 17].

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) arises when the physiological coagulation mechanisms that lead to thrombin and plasmin formation are triggered by pathological mechanisms in an unlocalized fashion. That is, the clotting process is not limited to wound surfaces, but it is disseminated throughout the vasculature.

The trigger that starts the procoagulant and fibrinolytic process varies. For example, amniotic fluid, brain tissue or Gram negative bacteria can directly activate the early coagulation pro-enzymes; hypotension can also initiate DIC from direct hypoxic endothelial damage that exposes tissue thromboplastin to tissue factor and plasma plasminogen to tissue plasminogen activator.

DIC may manifest clinically as: a widespread thrombotic disorder, with distal gangrene and other organ infarctions, particularly manifesting as acute renal failure; a primarily haemorrhagic disorder, caused by loss of platelets and soluble clotting factors, particularly fibrinogen, digested both by thrombin and plasmin; or a mixture of both. The severity varies from fulminant DIC with profound bleeding and thrombotic organ damage, to a mild thrombocytopenia and prolongation of clotting times that is manifest only on laboratory testing.

The heterogeneity of causes and manifestations may in part explain the lack of consensus in the management of DIC [83]. Heparin therapy has its advocates on the basis that inhibition of thrombin reduces the consumption of fibrinogen, other clotting factors and platelets, and both reduces the thrombotic element and improves the coagulation impairment. There have been no clinical trials reported that support this point of view; one clinical trial compared heparin with antithrombin III in a prospective trial in which there was no no-treatment arm. The patients treated with heparin fared worse [85].

The use of heparin in the treatment of DIC is uncommon in the U.K. Emphasis has tended towards management of bleeding or bleeding potential by correcting thrombocytopenia and deficiencies of fibrinogen and other soluble clotting factors [12, and British Committee for Standards in Haematology, in preparation], particularly the cofactors V and VIII:C, which are themselves proteolysed by plasmin. The optimum use of blood products has not been defined for DIC; however, there is no compelling evidence that suggests that replenishment of fibrinogen or platelets increases thrombotic complications of DIC, or that such products should be withheld from the surgical patient. Other products that may emerge for treatment of DIC in the future include the thrombin inhibitor, antithrombin III and the anticoagulant serine protease, activated protein C [67]. The main therapeutic objective remains rapid eradication of the precipitating cause.

An ideal therapy for DIC would be a process that impaired the pathological activity of thrombin and plasmin without impairing their physiological activities. Antithrombin III and protein C are the closest current approaches to this ideal, and further clinical studies may establish their role in this perplexing and difficult spectrum of disorders.

Liver Transplant

Orthotopic liver transplantation is accompanied by a complex coagulopathy arising from the procedure itself, complicated by the existence of a preoperative haemostatic defect that accompanies end-stage liver disease and, in some patients, hypersplenism. Liver failure *per se* is associated with impaired production of the soluble coagulation factors II, V, VII, IX, X and XI and fibrinogen, and with deficient synthesis of plasminogen and its inhibitor, alpha-1 antiplasmin. In addition, synthesis of the anticoagulant proteins C, S and antithrombin III is also reduced. A pre-existing consumptive coagulopathy or low-grade disseminated intravascular coagulation may also complicate the preoperative picture. This is because activated proteases of the coagulation pathway, together with fibrinogen degradation products, are normally cleared from the portal circulation by the liver.

Coagulopathy associated with liver failure is exaggerated during the anhepatic phase of the transplant operation. During this stage, significant fibrinolysis can result from increased tissue plasminogen activator inhibitor released from the hypoperfused distal tissues, and compounded by lack of hepatic synthesis of alpha-1 antiplasmin [20]. Thrombocytopenia may be present during the pretransplant phase, from both increased consumption and sequestration, associated with the consumptive coagulopathy and hypersplenism, respectively. These coagulopathies may be complicated further by the effects of massive transfusion.

The reasons for increased tPA activity during the anhepatic phase are uncertain and may be related to increased secretion from endothelial cells in response to the venovenous bypass procedure or hypothermia, to release of tPA from damaged tissues, or to reduced clearance of tPA as a result of the absence of hepatic function [4].

Following reperfusion of the donor liver, the coagulopathies resolve at a variable rate.

Monitoring haemostatic function in patients undergoing liver transplantation

Keeping pace with the profound and variable changes in haemostatic function during the operative stages of liver transplant is difficult. The 20–30 min that it takes to perform simple coagulation screening is too slow to be of great practical use. Some centres [53, 69] have reported useful results using thromboelastography, a somewhat old-fashioned technique that gives a rapid picture of global coagulation which includes an assessment of platelet function.

Pharmacological treatment of coagulopathy at liver transplantation

Preliminary studies have suggested that aprotinin (Trasylol, Bayer) is effective in preventing the development of coagulopathy during orthoptic liver transplantation [53, 63]. This is discussed below.

Earlier studies suggesting that antithrombin III therapy reduced blood loss in liver transplantation have not been borne out by a prospective study [6]. Although improved inhibition of thrombin activation during the transplant procedure might be expected to have some beneficial effect, the major coagulopathy probably derives from plasmin activity, which would be influenced by aprotinin, but not by antithrombin III.

Cardiopulmonary Bypass

Recent studies have demonstrated that the use of large doses of the drug aprotinin reduces the blood loss and coagulopathy associated with cardiopulmonary bypass. The mechanism of action of aprotinin remains unclear and the failure of previous theories of the pathophysiology of coagulopathy caused by cardiopulmonary bypass to predict the effect of aprotinin, has cast considerable doubt on the validity of previous interpretations of the observed phenomenon.

Clinical studies

In 1987, Royston and co-workers reported that large doses of aprotinin, given to patients undergoing repeat cardiopulmonary bypass procedures for valve replacement, resulted in a considerably lesser degree of coagulopathy and reduced blood requirements compared with those of control patients [73]. Other studies have confirmed these findings and extended them to patients with septic endocarditis [66] and to patients who had ingested aspirin shortly before surgery [9]. Use of aprotinin in cardiopulmonary bypass surgery has since become widespread. Aprotinin had been used in cardiopulmonary bypass in the 1960s and 70s without convincing evidence of effect. The difference between present and current regimens is the dose used: currently a loading dose of up to 2000000 kallekrein inhibitory units (KIU) is used, followed by an infusion of 500000 KIU h^{-1} until the end of bypass, whereas formerly about 50% of this dose was used.

The investigators who described this effect of high-dose aprotinin on blood loss in cardiac surgery had not set out to look for one. Their intention had been to demonstrate a beneficial effect of aprotinin on pulmonary function after cardiopulmonary bypass.

Causes of coagulopathy in cardiopulmonary bypass in relation to the mechanisms of action of aprotinin

Many detrimental effects of cardiopulmonary bypass on the coagulation systems have been reported. The most prominent effects have been on platelets: loss of membrane structures and granule contents, and generation of activation markers on the platelet surface [2, 27, 60, 88, 89]. Additional observed effects have included activation of the fibrinolytic system and of the contact system, and activation of leucocytes with release of granule contents [14, 32, 38, 86, 87].

The mechanism of action of aprotinin in preventing the coagulopathy of cardiopulmonary bypass remains unclear. However, clinical studies have demonstrated or suggested a protective effect against haemorrhage in surgical situations other than cardiopulmonary bypass, including liver transplantation and vascular surgery [53, 84]. This suggests that the effect of aprotinin is not limited to cardiopulmonary bypass alone, and that it is not attributable to prevention of platelet activation in the pump mechanism. Future data may indicate that use of aprotinin leads to amelioration of physiological haemostasis in other conditions.

The fact that previous observations or measurements of the function of the coagulation systems did not lead directly to the conclusion that a protease inhibitor would prevent the changes induced by cardiopulmonary bypass, indicates that many or all such observations were of events downstream to some initial event that is preventable by aprotinin. Until such time as monofunctional drugs are available that selectively impair one enzymatic function at one site in the coagulation system, the site of action of aprotinin will remain speculative. Notwithstanding this, a likely candidate for future examination of the prime site of action of aprotinin is platelet membrane GPIb. Van Oeveren and colleagues [65] have shown that loss of GPIb is an early event during cardiopulmonary bypass that is prevented by aprotinin in clinical studies.

As GPIb–von Willebrand factor adhesion is of fundamental importance in the very early stages of coagulation, it is possible that its preservation on the surface contributes to the haemostatic effect of aprotinin. In addition, GPIb contains the thrombin binding site involved in thrombin-induced activation of platelets [36], so that subsequent ability of platelets to respond to thrombin stimulation is possibly increased. Perhaps of more importance, hydrolysis of GPIb by aprotinin-inhibited enzymes generated during the coagulation/fibrinolysis processes may itself result in platelet activation. The prevention of such activation may preserve the circulating platelets from further damage in the bypass circuit. This is because platelets will not then have on their surface functional fibrinogen binding sites (induced by prior activation) that would promote binding of platelets to fibrinogen deposited in the bypass tubing.

GPIb is a transmembrane heterodimer; the external portion is readily cleaved from the platelet surface by plasmin, elastase and calpain. All of these enzymes can be inhibited by aprotinin, and all are direct platelet agonists in addition to, or perhaps because of, their ability to cleave GPIb.

Plasmin. Plasmin activity in cardiopulmonary bypass has been demonstrated in several studies [86]. This activity can be generated through tissue plasminogen activator from endothelial cells or from scar tissue at sternotomy or other surgical procedure, or through activation of the contact system. Contact system activation does occur during the bypass phase: its role is unclear in the generation of coagulopathy or in the prevention of that coagulopathy by aprotinin, as the presence of bypass circuitry may not be essential for aprotinin to have a haemostatic effect. However, it is important to note that both plasminogen and a plasminogen activator, SCU-plasminogen activator, are present on the platelet surface [56, 70]; in the presence of kallekrein generated by the contact system, plasmin could be generated directly on the platelet surface by direct activation of SCU-plasminogen activator.

Elastase. Neutrophil elastase is generated from activated neutrophils during cardiopulmonary bypass. Elastase can cleave GPIb and is a direct platelet agonist [40]. It is inhibited by aprotinin [25], but at greater concentrations than are required for inhibition of plasmin.

Calpain. Calpain is a cysteine protease present in many cells including red cells and platelets, where it comprises about 2% of total platelet intracellular protein. It is present in active form on the surface of thrombin-stimulated platelets and, possibly, plasmin-stimulated platelets [15]. It can cleave GPIb from the platelet surface *in vitro* [51] and *in vivo* [58], and is a direct platelet agonist. In addition, it cleaves the ADP receptor, aggregin [15]. It is inhibited by aprotinin in solution [52] and on the platelet surface [59].

Other mechanisms by which aprotinin could contribute to improved haemostatic function

By preventing dissolution of formed fibrin clots (through its ability to inhibit plasmin) or by preventing the self-inhibition of thrombin via protein C [22], aprotinin could improve clot formation and prevent its dissolution. Any benefit from such activity is likely to be modest. Fibrinolysis is usually normal at the end of bypass [32] and fibrin generation is not significantly impaired.

In conclusion, aprotinin may exert its effect by one or more of several mechanisms. Exploration of events occurring very early in the coagulation systems is likely to be most informative; inhibition of tPA-induced plasmin on the platelet surface could account for much or all of the observed benefit.

Coagulopathy Complicating Rupture of Abdominal Aortic Aneurysm

Mortality from ruptured abdominal aortic aneurysm has been strongly associated with coagulopathy and uncontrollable haemorrhage [29, 55, 57]. This mortality has risen progressively over the past 20 years [24, 62] and is the commonest life-threatening emergency in vascular surgery and a major consumer of surgical intensive care resources [G. C. Davies, personal communication]. In those patients who reach hospital, the operative mortality is in the range 21–70%, with a mean of about 50% [16, 68, 76]. After operation, haemorrhage and multi-system organ failure are major causes of morbidity and mortality [29, 30].

While the development of coagulopathy is causally associated with other conditions contributing to increased risk (including time for resuscitation, larger surgical bleeds, more extensive surgical procedures and renal failure) the development of excessive bleeding has been reported as an important cause of death in these patients [29, 55, 57]. The abnormal bleeding is the result of disseminated intravascular coagulation or dilution of procoagulant factors, or a combination of both. Clinical observations suggest that there are two categories among these patients who present with ruptured abdominal aortic aneurysm. The first group has a low mortality rate and may be considered to be well managed by current therapy [3, 80]. The second patient group has a mortality of 70–100% [80]. Early identification of these high risk patients at an early stage offers a prospect of trialling new and, if necessary, radical approaches to management.

In a recent prospective study [7], 23 consecutive patients with ruptured aneurysms had a coagulation screen performed immediately on admission to the accident and emergency department: six of 13 patients with an abnormal screen died, compared with none of 10 patients with normal screens ($P = 0.04$, chi-square test with Yates' correction). These observations are similar to previous published experience in which the mortality of patients with acquired coagulopathy was 11 of 15 [29], eight of nine [55] and four of four patients [57].

It remains to be demonstrated that correction of coagulopathy present on admission in these patients will result in improved outcome. Previous attempts to prevent the onset of coagulopathy in surgical patients receiving massive transfusion using prophylactic platelet transfusions and fresh frozen plasma have not been successful. However, it is possible that early and aggressive attempts to reverse the tissue hypoxia and prevent the subsequent coagulopathy in these patients may result in an overall improvement in outcome.

USE OF FIBRIN GLUE AS A HAEMOSTATIC AGENT IN SURGERY

Fibrin glue has been used in a wide range of surgical procedures. It works by a simple process. Direct application of formed fibrin onto the bleeding site bypasses physiological requirements for haemostasis. The glue is prepared as two separate solutions, one of fibrinogen and the other of thrombin. These two agents are mixed at or near the required site of action and rapidly form an adherent fibrin plug. The rate of formation of fibrin can be regulated by altering the concentration of thrombin. Fibrin glue may delay nerve and bone repair [49, 61], but other potential complications such as viral transmission, adhesion formation and unwanted thrombosis remain theoretical.

Fibrin glue has been reported to be effective in cardiovascular and general vascular surgery, in paediatric cardiovascular surgery and in thoracic, plastic, oral, ENT, neurosurgical, splenic, hepatic and orthopaedic surgery [5, 11, 23, 31, 33, 39, 41–43, 46, 48, 50, 54, 61, 64, 71, 78, 79, 81, 82, 90]. The evidence for its efficacy has been compelling, especially where fibrin sealant has been used in surgery in patients with acquired or congenital coagulation disorders [41,48]. However, prospective controlled clinical trials have been few and benefit has often been reported by anecdote or impression.

A large prospective clinical trial of fibrin sealant was reported by Rousou and colleagues [72]. Patients undergoing sternotomy were allocated randomly to receive either treatment with fibrin sealant (Tisseel, Immuno AG, Austria) or conventional haemostatic topical agents (Avitene, Gelfoam, Oxycel, Surgicel, or Thrombinar). A success rate of more than 90% was reported in achieving haemostasis within 5 min from the fibrin sealant, regardless of whether the patient had received heparin. In comparison, a 12.4% success rate was achieved with conventional therapy.

CONCLUSION

It is now apparent that it is possible to augment physiological haemostasis in surgical patients by pharmacological means including aprotinin and fibrin sealant. The next few years may see an extension of these techniques to many surgical fields.

SHORT COMMUNICATIONS

LONG-TERM BACKACHE AFTER EXTRADURAL OR GENERAL ANAESTHESIA FOR MANUAL REMOVAL OF PLACENTA: PRELIMINARY REPORT

R. J. VICKERS AND A. E. MAY

A questionnaire designed to investigate the incidence of newly acquired, long-term backache was sent to women who had previously undergone manual removal of the placenta during a 12-month period in one maternity hospital. There was a significantly greater incidence of long-term backache in patients who had extradural anaesthesia specifically for manual removal of the placenta compared with patients receiving a general anaesthetic for the same procedure. The results of this retrospective study in a small population warrant examination in a large, prospective, controlled investigation. (Br. J. Anaesth. 1993; **70**: 214–215)

KEY WORDS

Anaesthesia, general. Anaesthesia, obstetric. Anaesthetic techniques: extradural. Complications: backache.

A large retrospective study examining the incidence of long-term backache after childbirth found that the incidence was significantly greater in those patients who had an extradural sited during labour than in those who had either no extradural during labour or an extradural sited only for an elective Caesarean section [1]. The authors postulated that the increased incidence of backache after an extradural in labour resulted from inadvertent stressed posture resulting from the combination of effective analgesia and muscle relaxation.

To clarify further the relative significance of stressed posture, labour and extradurals in the causation of long-term backache, we have examined the incidence of long-term backache after extradural and after general anaesthesia for manual removal of placenta. Patients in this group would not have had the combination of stressed posture and extradural analgesia in labour.

PATIENTS AND RESULTS

The study was approved by the local Ethics Committee. A questionnaire was sent in September 1991 to all patients recorded in the birth register as having undergone manual removal of the placenta between March 1, 1990 and February 28, 1991.

The questionnaire comprised the following:

1. What type of anaesthetic did you have?
   General (put to sleep) — Extradural (injection in back)
2. If you had an extradural, when was it put in?
   Before delivery of baby/after delivery of baby

Since delivery, have you had any of the following problems:

3. *Headache* Yes/No
   (If "no" go to Question 4)
   If "yes"
   How often do you get them
   Are they worse than before delivery? Yes/No
   Have you needed to see a doctor about them? Yes/No
4. *Backache*
   (If "no" go to Question 5)
   How long after delivery did the backache start?
   When did you stop having backache?
   Have you needed to see your doctor about it? Yes/No
   Had you ever seen a doctor about backache before you were pregnant this time? Yes/No
5. *Numbness in your legs* Yes/No
   If "yes"
   How long after delivery did it start?
   When did it end?
   Did you see a doctor about it? Yes/No

If no reply was received, a second identical questionnaire with a covering letter was sent in January 1992.

A total of 98 questionnaires were sent. There was a response of 68 replies to the first mailing and a further eight to the second. This total of 77 replies represents a response rate of 78.57%.

The questionnaires revealed that, of the 77 responders, 19 had a general anaesthetic and 55 had an extradural for manual removal of the placenta. Of these 55, 17 had the extradural sited in labour before delivery of the baby and 38 after. Of the remaining three, two received only Entonox for manual removal of the placenta and one had an unsuccessful extradural and required a general anaesthetic.

We have compared the 19 patients who had a general anaesthetic and the 38 patients who had an extradural anaesthetic sited specifically for manual removal of the placenta.

We defined significant backache as a period of at

TABLE I. *Incidence of backache in the two groups*

	General anaesthesia	Extradural anaesthesia
Total No. patients	17	33
Significant backache (No. (%))	1 (6.25)	11 (33.3)

least 6 weeks of backache occurring within 3 months of delivery [1]. None of the patients had previously suffered from backache, apart from one who had a general anaesthetic. Two patients who had undergone general anaesthesia and five patients who had undergone extradural anaesthesia after delivery of the baby gave insufficient information in response to the questionnaire to determine if the backache was significant (as defined above). These eight patients were excluded from analysis.

There was a significant difference in the incidence of backache between the two groups ($P = 0.04$, Fisher's exact probability test) (table I).

COMMENT

Backache is a common problem; according to the U.K. Department of Health, 46.5 million working days are lost each year. Amongst female sufferers, many trace the onset of backache to childbirth, and some to extradural analgesia in particular, but this has not been subjected to close examination.

Large numbers of extradural blocks are performed in the peripartum period, but little is known about the incidence of long-term effects from such blocks. MacArthur and colleagues [1] have published the only study on long-term backache after extradural analgesia in labour. They found that those women who had received an extradural block in labour had a significantly greater incidence of long-term backache. However, this study was retrospective and not randomized. The lack of data on extradural blocks in obstetrics from prospective randomized trials has been highlighted recently [2].

In this study, we have found a significant difference in the incidence of backache between those undergoing general anaesthesia and those having an extradural for manual removal of placenta. This suggests that the increased incidence of long term backache was caused by the extradural block itself and not stressed posture as suggested by McArthur and colleagues [1]. However, our study suffers from the limitations of being small, retrospective and not randomized. Whilst it would be difficult to randomize patients, during labour, to receive extradural analgesia or another mode of analgesia, it should be possible for manual removal of placenta. The purpose of publishing our preliminary data is to draw attention to this important problem and encourage the performance of large-scale prospective, randomized studies to determine if long-term backache is a real and important sequela of extradural analgesia in obstetric practice.

CLINICAL EVALUATION OF THE OESOPHAGEAL HEAT EXCHANGER IN THE PREVENTION OF PERIOPERATIVE HYPOTHERMIA

P. KULKARNI, A. MATSON, J. BRIGHT, J. PEARSON AND F. CARLI

SUMMARY

We have studied the efficiency of an oesophageal warming device in the prevention of perioperative hypothermia in 22 patients undergoing total hip replacement. Aural canal and skin temperatures (15 sites) were measured before induction of anaesthesia, at the end of surgery and 1 h after recovery and mean body heat was calculated to quantify heat distribution. Core temperature decreased significantly in both groups at the end of surgery, by a mean of 1.8 °C in the control group and 1.3 °C in the oesophageal heat exchanger (treated) group (P = 0.09). In contrast, mean skin temperature at the end of surgery increased by a median value of 0.26 °C in the treated group and decreased by 1.02 °C in the control group (P = 0.03). Both groups of patients lost body heat to the same extent (P = 0.34). Thus the oesophageal heat exchanger was ineffective in preventing perioperative hypothermia in a group of patients undergoing total hip replacement. (Br. J. Anaesth. 1993; **70**: 216–218)

KEY WORDS

Hypothermia: perioperative. Equipment: oesophageal warmer. Temperature: body.

Heat loss can occur during anaesthesia and surgery, and the resultant hypothermia might lead to increased morbidity and mortality, especially in the high risk population, such as the elderly with poor cardiovascular reserves [1].

The oesophagus is a convenient site for core (central) warming in anaesthetized patients, being easily accessible and situated in close proximity to the major blood vessels, thus acting as a good conduit for heat transfer. An oesophageal thermal device has been designed and shown to be effective in delivering heat and in the prevention of perioperative hypothermia [2].

We have examined the efficacy of the oesophageal warming device in the prevention of perioperative hypothermia in patients undergoing total hip replacement in a cool operating environment, by measuring core (tympanic) and skin temperatures at 15 sites.

METHODS AND RESULTS

After obtaining Ethics Committee approval and informed consent, we studied 22 patients (ASA I and disease, undergoing elective unilateral total hip replacement. They were randomly allocated to two groups: a control group ($n = 11$) (median age 73 yr (range 34–83 yr); weight 64 kg (range 48–90 kg)), with no active warming technique in the intraoperative period and a treated group ($n = 11$) (median age 71 yr (range 52–82 yr); weight 66 kg (range 46–90 kg)) using the oesophageal heat exchanger system.

The oesophageal thermal tube (Granulab, Pennco Medicals Ltd, London) was tested before each study for water leaks, obstruction in the connections and any evidence of damage. After induction of anaesthesia and tracheal intubation, a well lubricated oesophageal thermal tube was inserted and placed in the oesophagus. The oesophageal heat exchanger was connected to a MicroTemp water heating pump (SeaBrook Medical Inc.), set at 50 litre h^{-1}, to give a temperature of 40 °C (range 38–41 °C) in the oesophageal tube. The heating was commenced before surgical incision and was maintained until the end of surgery, when the oesophageal warming device was removed. The median duration of surgery was 103 min.

The patients were premedicated with i.m. papaveretum 10–15 mg 1 h before surgery. All patients received general anaesthesia comprising thiopentone, pancuronium, nitrous oxide in oxygen and enflurane (inspired concentration 1–1.3%). Hartmann's solution was infused i.v. at room temperature and blood, if required, was transfused after being warmed to 37.0 °C.

Tympanic temperature was recorded with the MON-A-THERM (Mallinckrodt) temperature probes, calibrated in the temperature range of 25–40 °C and accurate to 0.1 °C. Skin temperatures were measured at 15 points, using the Infra-red Radiation Thermometer (Minolta Cyclops 33), obviating the need for placing temperature probes on the skin [3].

Temperature readings were taken before induction

of anaesthesia, at the end of surgery but before antagonism of neuromuscular block and 1 h into recovery for both groups of patients. Other data recorded were the operating theatre temperature (median 20 °C) and the relative humidity. The mean skin temperature (MST) was calculated using the modified unweighted 15 sites formula of Hardy and DuBois [4, 5]. The 15 sites were: forehead, face, neck, nipple, mid arm, mid forearm, dorsum of hand, anterior abdomen, iliac crest, mid thigh (medial and lateral), knee, mid calf (medial and lateral) and the dorsum of the foot. Total body heat (TBH) was calculated from mean body temperature (MBT):

$$\text{MBT (°C)} = (0.66 \times \text{aural canal temp.}) + (0.34 \times \text{MST})$$

$$\text{TBH (kJ)} = \text{MBT} \times \text{body weight (kg)} \times 0.83\ \text{(specific heat)} \times 4.186$$

The changes in the core and skin temperatures and TBH during the period before induction to after surgery and 1 h after recovery were compared between the control and the treated group, using Mann–Whitney tests.

There was a significant decrease in core temperatures in both groups; however, there was no difference between the groups ($P = 0.09$). There was a decrease of 1.02 °C in the mean skin temperature during surgery in the control group; in the treated group, an increase of 0.26 °C was observed for the same period ($P = 0.03$). This was followed, in recovery, by an increase in mean skin temperature in the control group compared with the treated group ($P = 0.004$). There were similar changes in total body heat content in both groups during the study (table I).

COMMENT

We have found that the oesophageal heat exchanger was ineffective in preventing the decrease in core temperature and body heat content during hip surgery. However, measurement of surface skin temperatures at 15 sites in the treated group showed an increase in mean skin temperature at the end of surgery.

In spite of its bulk, the oesophageal warming device was easy to insert and there was no trauma to oesophageal tissue. The exact location in the oesophagus could be checked and, because of its design, rapid warming of the surrounding structures could be achieved. Nevertheless, core temperature decreased by more than 1 °C in the treated group. One possible explanation for this change may be the fact that the lower one-third of the oesophagus is less perfused than the surrounding structures. In addition, the pressure exerted by the rubber sheath on the oesophageal wall might affect heat transfer. Thus, although the device is in close proximity to large vessels, it may not be the most efficient site for transferring heat to the rest of the body. Another reason for the observed decrease in core temperature could be the low operating theatre temperature (19–20 °C in this study), leading to considerable heat loss from the periphery in the form of cutaneous heat flux. The distribution and transfer of body heat through the skin in relation to the environmental temperature plays a considerable part in temperature homeostasis.

The decrease in core temperature observed in the oesophageal heat exchanger group at the end of surgery was associated with increased mean skin temperatures, which would suggest a response to core warming and a consequent redistribution of body heat to the periphery. A similar response to core warming has been reported previously, in a similar population undergoing hip arthroplasty in a cool environment [6]. However, those patients were warmed actively by means of a heated humidifier, set at 40.0 °C, in the breathing system. Their mean skin temperature increased significantly, by 0.7 °C, while the decrease in core temperature was very small (0.3 °C). These findings would, therefore, indicate the importance of efficient and adequate core warming to attenuate radiation heat loss; this was not achieved efficiently in our study using the oesophageal heat exchanger.

ACKNOWLEDGEMENT

We thank Pennco Medical Ltd, London, for supplying the oesophageal warming devices used in this study.

EFFECTS OF LORAZEPAM ON OXYGEN SATURATION BEFORE CARDIAC SURGERY

J. S. S. POLLOCK AND G. N. C. KENNY

SUMMARY

*We have studied patients presenting for coronary artery bypass surgery on two nights before surgery. Oxygen saturation during a night when the patient received no night sedation was compared with the night before surgery, when lorazepam 3–4 mg was given. There was no difference between the two nights when the total time at oxygen saturations less than 90% were compared, but the minimum oxygen saturation value when the patient received lorazepam was significantly smaller. No patient had significant sleep apnoea. (*Br. J. Anaesth. 1993; **70**: 219–220)

KEY WORDS

Hypnotics, benzodiazepines: lorazepam. Oxygen: saturation. Premedication: night sedation.

Angina and hypertension have been reported to occur in patients with sleep apnoea syndrome [1]. Patients presenting for coronary artery bypass surgery have angina and often have treated hypertension. Benzodiazepines are often prescribed, but these drugs are known to worsen pre-existing oxygen desaturation [2]. The aim of the present study was to compare the oxygen saturation and frequency of apnoea during a night when the patient received no sedation, with the night before bypass surgery when lorazepam was prescribed.

METHODS AND RESULTS

Informed consent was obtained from 17 male patients (age range 48–63 yr; weight range 64.5–83.7 kg) undergoing elective coronary bypass surgery. Patients who had significant respiratory disease were excluded. An oximeter (Biox 3700, Ohmeda) finger probe was attached to the patient before sleep and the output connected to an Atari computer, during a night when the patient received no sedation.

The oxygen saturation and heart rate were recorded to disc by a program which recorded oxygen saturation values every 3 min, unless the value decreased by more than 5% from the baseline, when data were recorded every 10 s until the patient awoke in the morning.

The patients received lorazepam 3 or 4 mg on the night before surgery and a second night's recording was obtained. The results were analysed to determine the percentage of the time spent at oxygen saturation values greater and less than 90%. The baseline oxygen saturation and the minimum oxygen saturation recorded were compared between the two nights. Data from the unsedated (normal) night and the sedated night were analysed using Student's paired *t* tests and Spearman's rank correlation test as appropriate.

Two patients were excluded from the results: one had unsatisfactory recordings caused by probe failure and the second had pulsus bigemini and a heart rate of less than 45 beat min^{-1} which gave inaccurate oxygen saturations.

Of the remaining 15 patients, six gave a history of treated hypertension and nine had a previous infarct. No patient gave a history of sleep apnoea; four patients did not snore and one patient was a severe snorer.

The oxygen saturation results (table I) were analysed to determine the percentage of time spent at oxygen saturations greater and less than 90%. During the sedation night, there was no difference in the total percentage time that the patients spent at oxygen saturation greater than 90%, compared with the non-sedated night. Two patients had oxygen saturations less than 90% for lengthy periods: one improved his oxygen saturation during the lorazepam night, while the other had smaller values. The mean minimum oxygen recorded value during the sedation night was significantly less than the non-sedated night ($P < 0.05$). Ten patients decreased their minimum value, three remained at the same value and one patient recorded a greater minimum oxygen saturation.

TABLE I. *Mean* (SD) *percentage of the total time spent at oxygen saturation* (Sp_{O_2}) *greater or less than 90% and the minimum* Sp_{O_2} *recorded.* *$P < 0.017$ *compared with normal night*

	Time (%) spent at		
	$Sp_{O_2} > 90\%$	$Sp_{O_2} < 90\%$	Min. Sp_{O_2} (%)

Accepted for Publication: September 17, 1992.

*Present address: Department of Anaesthesia, Victoria Infirmary, Langside Road, Glasgow G42 9TY.

No patient had significant sleep apnoea (defined as more than five oxygen saturation decreases, lasting 10 s or more in 1 h, the oxygen saturation decrease being 5 % or more from the patient's baseline oxygen saturation).

COMMENT

Patients who suffer hypertension have been shown to have an increase in sleep apnoea [3], while habitual snoring, a symptom of sleep apnoea, has been associated with angina, hypertension and ischaemic heart disease [1, 4]. In these patients, the ensuing oxygen desaturation from sleep apnoea may contribute to myocardial ischaemia [5]. Obstructive sleep apnoea, the most common type of sleep apnoea, has an increased frequency in males and in the age range 40–60 yr. These ages are similar to those of patients presenting for coronary artery bypass.

We found no patient with sleep apnoea, possibly because several of the patients developed angina after a myocardial infarction, rather than having a long history of progressing angina culminating in the need for coronary artery bypass. Hypertension in other patients was discovered at the time of infarction and may or may not have been present before the infarction. Coronary artery disease is multifactorial and the part that sleep apnoea plays in hypertension and angina remains to be determined.

A premedication regimen of lorazepam, morphine and droperidol in CABG patients has been found to decrease oxygen saturation [6] and to be associated with new ECG changes indicating further ischaemia in some patients. In the present study, lorazepam did not worsen the overall oxygen saturation during the sedation night, although one patient who had severe snoring, had a decreased oxygen saturation. In patients with a history of heavy snoring, this may indicate decreased oxygen saturation values and the need for added oxygen if benzodiazepines are prescribed.

In this study, the minimum oxygen saturation values were reduced significantly compared with the values recorded during the sedation night. It has been recommended that oxygen supplementation be given to cardiac patients premedicated with an opioid and this regimen may be recommended also for patients who receive benzodiazepines.

EFFECTS OF MIDAZOLAM ON INSULIN SECRETION FROM ISOLATED RAT PANCREATIC ISLETS OF LANGERHANS

J. P. DESBOROUGH, P. M. JONES, S. J. PERSAUD AND S. L. HOWELL

SUMMARY

Isolated, cultured rat pancreatic islets of Langerhans were incubated in medium containing glucose 2 or 20 mmol litre^{-1} and with glucose supplemented with midazolam 10, 100 or 1000 ng ml^{-1}. Glucose 20 mmol litre^{-1} with the addition of noradrenaline 10 µmol litre^{-1} was used as a control. In contrast with noradrenaline, midazolam did not inhibit glucose-induced insulin secretion. Noradrenaline 10 µmol litre^{-1} inhibited secretion to basal values in response to glucose 20 mmol litre^{-1} ($P < 0.001$). (Br. J. Anaesth. 1993; **70**: 221–222)

KEY WORDS

Hormones: insulin. Hypnotics, benzodiazepines, midazolam.

Midazolam facilitates the effect of the inhibitory neurotransmitter γ-aminobutyric acid (GABA). In a recent clinical study [1], circulating concentrations of insulin were found to be decreased significantly after induction of anaesthesia with midazolam 0.42 mg kg^{-1} over 5 min; a control group of patients received a sleep dose of thiopentone, after which serum concentrations of insulin were unchanged. Benzodiazepine receptors have been demonstrated in rat pancreatic tissue [2] and GABA has been found in both rat and human pancreatic islets [3], although at present there is no consensus on the effects of GABA agonists on the insulin secretory response [4]. It was suggested [1] that a possible cause of the decrease in serum insulin concentrations seen clinically after midazolam could be direct inhibition of insulin secretion. In this study, we have investigated the effects of midazolam on glucose-stimulated insulin secretion from isolated rat pancreatic islets *in vitro*.

METHODS AND RESULTS

Islets were isolated from Wistar rats (150–200 g) by collagenase digestion of the pancreas [5]. In some experiments, islets were cultured overnight as described [5], in RPMI 1640 medium supplemented with streptomycin 100 µg ml^{-1}, penicillin 100 u ml^{-1} and fetal calf serum (10% v/v), and maintained at 37 °C in an atmosphere of 5% carbon dioxide in air. After 24 h, the islets were harvested and washed with a bicarbonate-buffered physiological salt solution, pH 7.4, supplemented with bovine serum albumin 0.5 mg ml^{-1} and calcium chloride 2 mmol litre^{-1}. Basal insulin secretion was measured in buffers containing glucose 2 mmol litre^{-1} and secretion was stimulated by the presence of glucose 20 mmol litre^{-1}. The effects of midazolam on insulin secretion were investigated by the addition of midazolam 10, 100 and 1000 ng ml^{-1}. The effects of noradrenaline, a potent inhibitor of insulin secretion via alpha$_2$ receptors [5], were also assessed. The islets were incubated for 60 min at 37 °C, sedimented by centrifugation (9000 *g*, 15 s) and supernatant samples stored at −20 °C until assay. Insulin was measured in the samples by radioimmunoassay using guineapig anti-insulin serum, purified rat insulin as standard and ^{125}I-labelled bovine insulin. For each experiment, samples were analysed in a single assay and the intra-assay coefficient of variation was 5.2%. Results are expressed as mean (SEM); $n = 7–9$. Differences between groups were analysed by unpaired Student's *t* test and considered significant when $P < 0.05$.

In experiments using freshly isolated islets, basal insulin secretion (glucose 2 mmol litre^{-1}) per islet was 1.83 (0.49) ng h^{-1} and glucose-stimulated secretion (20 mmol litre^{-1}) per islet was 6.05 (0.74) ng h^{-1} ($P < 0.01$). Midazolam 100 and 1000 ng ml^{-1} had no effect on glucose-stimulated secretion: 4.35 (0.75) ng h^{-1} and 5.64 (0.52) ng h^{-1}, per islet, respectively. As the collagenase isolation of islets may damage islet B-cell surface receptors, islets were cultured for 24 h to allow for receptor regeneration.

TABLE I. *Mean* (SEM) *insulin secretion from cultured rat islets of Langerhans.* **$P < 0.001$ compared with glucose alone. NA = noradrenaline. Basal secretion = in response to glucose 2 mmol litre^{-1}; glucose-stimulated = in response to glucose 20 mmol litre^{-1}*

	Basal secretion (ng h^{-1} per islet) ($n = 7$)	Glucose stimulated (ng h^{-1} per islet) ($n = 9$)
Glucose alone	2.09 (0.69)	4.35 (0.52)
Midazolam (ng ml^{-1})		
10	2.53 (0.46)	4.23 (0.78)
100	2.03 (0.37)	4.38 (0.43)
1000	1.37 (0.27)	3.65 (0.35)
NA 10 µmol litre^{-1}	1.31 (0.20)	1.33 (0.13)*

The results of two experiments using cultured islets are shown in table I. Basal insulin secretion in the presence of glucose 2 mmol litre^{-1} was not affected significantly by midazolam or noradrenaline. Glucose-induced secretion was not altered significantly by the presence of midazolam in the incubation buffer, but the addition of noradrenaline 10 µmol litre^{-1} caused complete inhibition of glucose-induced insulin secretion ($P < 0.001$ compared with glucose 20 mmol litre^{-1} alone).

COMMENT

Although caution must be exercised in making comparisons between species and in extrapolating from *in vitro* preparations to clinical investigations, it appears unlikely that midazolam has any significant direct effect on insulin secretion, as this *in vitro* study showed no effect of any of three concentrations of midazolam on basal or glucose-induced insulin secretion from cultured islets.

Catecholamines cause marked inhibition of insulin secretion from isolated islets of Langerhans [5]. This is thought to be mediated directly via alpha-adrenergic adrenoceptors on the islet cells. In this study, we used noradrenaline 10 µmol litre^{-1} as a control for the inhibition of glucose-induced insulin secretion, to demonstrate that cell surface receptors and the appropriate intracellular signal transduction systems were present in the cultured rat islets.

The concentrations of midazolam used in this *in vitro* study were based on previous reports of values obtained clinically in patients receiving the drug as an anaesthetic for major surgery [6]. Regimens for total i.v. anaesthesia using midazolam are based upon obtaining a steady state concentration of about 300 ng ml^{-1}. Similar concentrations of midazolam have been found to provide satisfactory anaesthesia in combination with fentanyl during abdominal surgery. However, peak values after i.v. bolus injection of midazolam 0.3 mg are about 900 ng ml^{-1}, and serum concentrations of midazolam in critically ill patients with reduced organ perfusion may reach several thousand ng ml^{-1}.

Previous studies of the effects of GABA agonists on insulin secretion have had variable results [4]. To summarize: neither GABA itself or GABA agonists appear to affect insulin secretion from islets directly. Studies in the dog have shown inhibition of secretion, whereas two human studies suggest that GABA may enhance basal and glucose-stimulated insulin secretion.

As it appears that midazolam does not directly inhibit insulin secretion, alternative explanations must account for the results obtained in the previously reported clinical study using midazolam [1]. It is possible that, in some patients, extremely large serum concentrations of the benzodiazepine were produced after i.v. injection of midazolam 0.42 mg kg^{-1} over 5 min. As insulin secretion is inhibited by catecholamines, an increase in circulating concentrations of adrenaline or release of noradrenaline from sympathetic nerve endings may impair insulin release from the pancreas. Circulating concentrations of catecholamines were not measured in the clinical study [1], but indirect evidence of sympathetic activity, as shown by values of mean arterial pressure and heart rate, were not significantly different between patients who received midazolam and the control group [1]. Variations in circulating concentrations of the counter-regulatory hormones, cortisol and adrenaline, mediate metabolic changes which may have had secondary effects on insulin secretion.

In conclusion, we have demonstrated that midazolam did not directly inhibit glucose-stimulated insulin secretion from an *in vitro* rat islet preparation. In this respect, our results with midazolam were similar to those obtained using other GABA agonists and GABA itself.

CASE REPORTS

VISUALIZATION OF EXTRADURAL BLOOD PATCH FOR POST LUMBAR PUNCTURE HEADACHE BY MAGNETIC RESONANCE IMAGING

A. G. GRIFFITHS, S. C. BEARDS, A. JACKSON AND E. L. HORSMAN

SUMMARY

We describe a case of post lumbar puncture headache treated by extradural blood patch. Magnetic resonance imaging (MRI) demonstrated a large extradural haematoma extending over four spinal segments and extending out through the neural outlet foramina. There was significant compression of the thecal sac, supporting the theory that extradural blood patch causes tamponade at the site of dural puncture. The spread of clot was predominantly upwards from the injection site and subarachnoid extension of blood was also demonstrated. (Br. J. Anaesth. 1993; **70**: 223–225)

CASE REPORT

A 35-yr-old woman (gravida 2, para 1, weight 78 kg, height 164 cm) was admitted in established labour. One hour after admission, artificial rupture of membranes was performed. Extradural anaesthesia was requested and an initial attempt at extradural puncture was made at the L2–3 interspace, using loss of resistance to air with the patient in the sitting position. During insertion of the needle, the patient moved suddenly and fluid was seen to drip through the Tuohy needle. The needle was resited at the L3–4 interspace without difficulty and an extradural catheter was inserted to a distance 3 cm in the extradural space. After negative aspiration, a test dose of 2% lignocaine 3 ml was injected through the catheter. This resulted unexpectedly in rapid onset of a bilateral sensory block to T7. Additional local anaesthetic agent was not administered and the catheter was removed immediately after delivery. The patient underwent uneventful vaginal delivery of a 4.04-kg male 80 min after insertion of the extradural catheter.

Twelve hours after delivery, the patient developed a severe postural headache radiating to the neck and a diagnosis of spinal headache was made. A 24-h trial of conservative treatment was unsuccessful and an extradural blood patch was performed 36 h after delivery.

After obtaining local Ethics Committee approval and informed consent from the patient, we performed an initial MRI scan of the lumbar spine. MRI was performed on a 0.5 Tesla GE MAX Scanner. Contiguous, 5-mm thick parasagittal T1 weighted gradient echo (GE 500/14) images were obtained throughout the lumbar spine to include the neural exit foramina on each side. A series of 5-mm axial T1 weighted images (GE 550/14) were also obtained, extending from T11 to the sacrum. All initial scans were normal (fig. 1).

MRI was followed by an uneventful extradural puncture at the L1–2 interspace with the patient in the sitting position, using loss of resistance to air. After injection of 18 ml of autologous venous blood into the extradural space, the patient experienced immediate relief of headache.

The MRI scan was repeated 30 min after injection of the blood patch, using the same imaging routines
